

Enhanced ST20 32-bit VL-RISC CPU

4 Kbyte data cache, 2 Kbyte SRAM

Unified memory interface

support for low-cost DVB-CI

• single transport stream input

integrated DVB, descrambler

Graphics/display

support for DVB transport streams

■ MPEG-2 MP@ML video decoder

2D paced blitter engine with fill function

blitter based display compositor

formats. Link-list control

• 200 MHz, single cycle cache, 4 Kbyte instruction cache.

• up to166 MHz,16-bit wide SDR SDRAM interface

four separately configurable banks, 8/16-bits wide

Programmable flash memory interface

SRAM, peripheral, Flash, SFlash[™] support

Programmable transport interface (PTI)

fully programmable horizontal and vertical SRCs.

 8 bpp CLUT graphics, 256 x 30 bits (AYCbCr) CLUT entries. 16 bpp true color graphics, RGB565, ARGB1555

STx5119

Low-cost interactive set-top box decoder

ADVANCE DATASHEET

PAL/NTSC/SECAM encoder

- RGB, CVBS, Y/C and YUV outputs with four 10-bit DAC outputs. RGB/CVBS or YUV/CVBS or YC/CVBS.
- encoding of CGMS, Teletext, WSS, VPS, close caption

Audio subsystem

- MPEG-1 layers I/II
- simultaneous MPEG audio decode on audio DACs and output of Dolby streams on S/PDIF
- IEC958/IEC1937 digital audio output interface
- integrated stereo audio DAC system

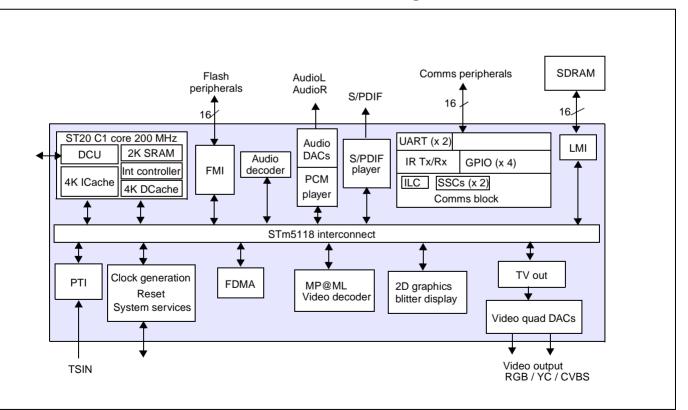

Central DMA controller

On-chip peripherals

- two ASCs (UARTs) with Tx and Rx FIFOs
- three 8-bit banks of parallel I/O and one 7-bit bank
- one smartcard interface and clock generator
- two SSCs for I²C/SPI master/slave interfaces
- infrared transmitter/receiver
- integrated VCXO
- low-power / RTC / watchdog controller

■ JTAG/TAP interface

■ Package 24 mm x 24 mm LQFP216

1 Applications

The STx5119 is the latest in the family of Omega2 set-top box ICs providing a high performance, low cost system on a chip for MPEG processing in cable, satellite or digital terrestrial STBs.

The STx5119 delivers enhanced performance with respect to previous generation devices. Main memory is based upon a single 16-bit external SDRAM.

The display architecture of the device is based on a high performance blitter engine which supports CLUT8 and RGB16 formats for video and OSD/graphics displays.

The STx5119 can be used for basic set-top boxes. A typical application is shown in Figure 1.

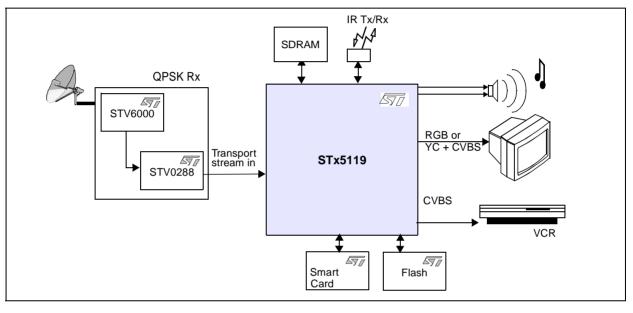

Figure 1: Free to air satellite

2 Audio and video summary specification

Table 1: Summary specification

Video decoder		
Feature	Description	
Video decode display	Based on the Omega2, provides a memory to memory decode into YC 4:2:0 macroblock format, provides simple resizing based on x2 and x0.5.	
Bit streams accepted	MPEG-1 video (ISO/IEC 11172-2), MPEG-2 video (ISO/IEC 13818-2) MPEG-2 Packetized elementary stream (PES) format as defined by ISO/IEC 13818-1 MPEG-1 ISO/IEC 11172-1 packets	
MPEG-2 profiles/levels supported	Main profile at main level (MP@ML), main profile at low level (MP@LL) Simple profile at main level (SP@ML)	
Maximum picture size	Width: 720 x 576 pixels = 45 x 36 Number of macroblocks: 45 x 36 = 1620	
Motion vector range	MPEG-1: -1024 to 1023 (full pel), -512 to 511.5 (half pel) horizontal and vertical MPEG-2: -1024 to 1023.5 horizontal and -128 to 127.5 vertical	
PTI compressed data input	Serial peak input rate: 100 Mbit/s	
SDRAM LMI interface	16-bit wide SDRAM interface. Peak bandwidth 532 Mbyte/s (133 MHz). Supports 64-Mbit, 64-Mbit, 64-Mbit, 128-Mbit, 256-Mbit, or 512-Mbit SDRAM. Fully cacheable address space for data and instructions, with cacheability controlled in 512 Kbyte blocks for up to 8 Mbytes.	
Start code detection	Automatic detection of start codes (of picture layer and above) to enable the microcontroller to access header data Counters provided for time-stamp tracking	
Decoding pipeline	Instruction register sets up each picture and defines pipeline operation Double-buffered quantization matrices enable loading of new tables concurrently with decoding	
Error concealment	Automatic concealment of errors detected by VLD and decoding pipeline by macroblock copy	

Table 1: Summary specification

Display	
Feature	Description
Video clock	27 MHz nominal
Video output	External pel clock Horizontal/vertical synchronization provided by internal digital encoder or external source Interlaced output 3:2 pull-down operation supported On-chip up-/down-sampling with anti-aliasing filter Vertical chroma reconstruction or luma filtering up to 5-tap filter
Pan and scan vectors	Horizontal: maximum vector size: 2047 pels, resolution: 1/8 pel Vertical: maximum vector size: 1022 lines, resolution: 1 line
On-screen display (OSD)	Blitter-based composition The OSD plane is managed as a set of horizontal bands with a specification comprising configuration, bitmap and, for CLUT formats, palette information for each region. The OSD operates in one of two modes, palette mode or true color mode. Palette mode : Each region can be independently specified with a resolution of 8 bpp. Regions are frame based. Each region palette can support up to 256 colors with up to 24 bits resolution per color entry. True color mode : Each region can be independently specified with a 16 bpp resolution in one of the following direct color formats: RGB565 and ARGB1555. A vertical interfield, antiflicker filter is provided to reduce flicker on interlace displays. It is available for both palette and true color modes.
Audio decoder	
Bit streams accepted	MPEG-1, layers I and II elementary streams
Performance	ISO/IEC 11172-3 Layers I and II All MPEG input bit rates supported with sampling rates of 32 kHz, 44.1 kHz and 48 kHz, free format at 32 kHz and 48 kHz sampling rates Decodes in single channel, dual channel, stereo, or joint stereo modes
Error concealment	Automatic error concealment on CRC or synchronization error detection
General	
Support for A/V sync	PTS/DTS extraction from MPEG packet layers with automatic association

3 Architecture features

3.1 Introduction

The STx5119 is a low-cost Omega2 MPEG device that delivers highly integrated features that provide an overall system cost reduction. The device implements a fully unified SDRAM based memory architecture and integrates the Omega2 video decoder cell together with a blitter engine and a multichannel DMA controller to provide enhanced performance for graphics and real-time stream transfers.

Transfer of data such as pixmaps, audio streams, stills and PES can be performed efficiently using the STx5119's DMA.

A true-color mode provides OSD graphics allowing the display of RGB16 formats: RGB565 and ARGB1555. This directly supports up to 65,536 colors in a region.

3.2 Omega2 (STBus) interconnect

The Omega2 multipath unified interconnect provides high on-chip bandwidth and low latency accesses between modules. The interconnect operates hierarchically, with latency-critical modules placed at the top level. The multipath router allows simultaneous access paths between modules, and simultaneous read and write phases from different transactions to and from the modules. Split transactions maximize the use of the available bandwidth.

3 Processor core

The ST20-C106 processor core is composed of the ST20C1+ CPU running at 200 MHz, a diagnostic controller unit (for low intrusion, real-time debugging), memory (4 Kbyte instruction cache, 4 Kbyte data cache and 2 Kbyte SRAM) and a 16 priority-level interrupt controller.

Memory subsystem

The STx5119 has a memory interface and a peripheral/flash interface.

The STx5119's local memory interface is used for all data requirements in unified memory applications including graphics, video and audio buffers. It provides 16-bit wide SDRAM support at up to 166 MHz.

The FMI provides support for 16-bit wide peripherals, flash and synchronous flash.

Instructions can execute in place from flash/SFlash[™] on the FMI or can be copied to SDRAM on the LMI. The following sections provide an overview of the different memory interfaces.

Local memory interface (LMI)

The LMI is a 16-bit wide SDRAM interface operating at up to 166 MHz. It supports 64-Mbit or 128-Mbit SDRAM. The LMI provides a fully cacheable address space for data and instructions, with data cacheability controlled in 512 Kbyte blocks for up to 8 Mbytes.

Flash memory interface (FMI)

The FMI provides a glueless interface to SRAM, flash, SFlash and peripherals, in up to four configurable banks over a 16-bit wide interface. Bus cycle strobe timings can be programmed from 0 to 15 phases for slower peripherals. Support is provided for control of DVB-CI.

3.5 Transport stream processing

The STx5119 supports single transport stream input. It is possible to support DVB-CI configurations as shown in Figure 2 and Figure 3.

Figure 2: Dual DVB-CI support

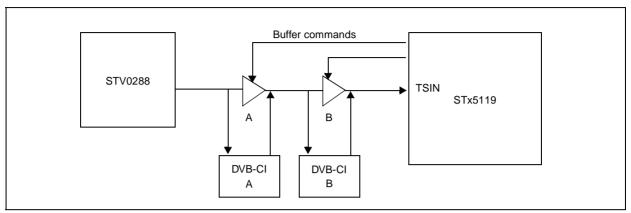

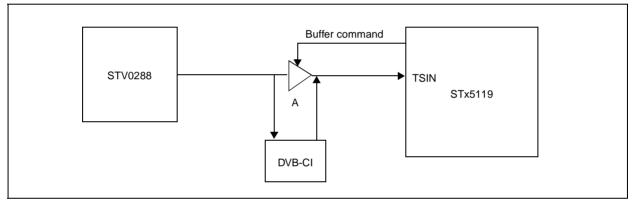

Figure 3: Single DVB-CI support

Programmable transport interface (PTI)

The PTI performs transport-stream descrambling, demultiplexing and data filtering. PES data is transferred by DMA to audio and video decoders via circular buffers. Section data is transferred by DMA to separate buffers for further processing by the CPU.

DVB transport streams can be handled by the PTI with data rates up to 100 Mbit/s.

The PTI performs PID filtering to select audio, video and data packets to be processed. 48 PID slots can be supported by the PTI.

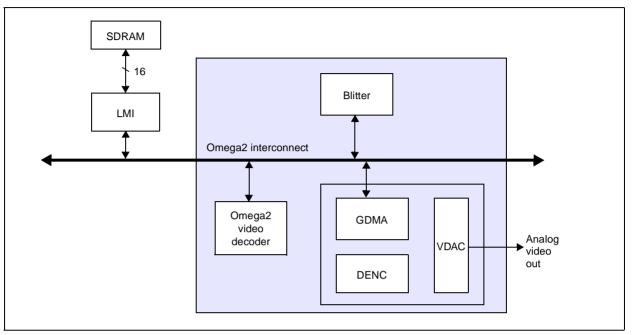

The PTI cipher descrambles DVB-CSA streams.

The PTI has a section filter core that filters DVB standard sections using 32 x 8-byte filters.

3.6 MPEG graphics and display processing

The MPEG graphics and display architecture shown in Figure 4 provides the graphics, videostream processing and display capabilities of the STx5119.

Video decode

The video decoder is based on the Omega2 cell and provides a memory to memory decode into YC 4:2:0 macroblock format. It is also able to provide simple resizing based on x2 and x0.5.

Graphics and display

Display

The STx5119 uses a blitter based display architecture, providing improved graphics and increased flexibility for building applications as illustrated in Figure 5

The following features are supported:

- SMART GUI,
- Picture in Graphic,
- mosaic channels presentation.

The composition is assisted by the 2D graphic hardware accelerator.

Graphics

The graphics operates in one of two modes:

- Palette modeEach region can be independently specified with a resolution of 8 bpp.Regions are frame based. Each region palette can support up to 256 colors
with up to 24 bits resolution per color entry.
- **True color mode** Each region can be independently specified with a 16 bpp resolution in either RGB565 or ARGB1555 direct color formats.

A vertical inter-field, anti-flicker filter is provided to reduce flicker on interlace displays. It is available for both palette and true color modes.

3.8 Digital encoder

The digital converter processes YCbCr 4:4:4/4:2:2 from main memory, which the blitter has generated, and produces a standard analog baseband PAL/SECAM/NTSC signal, and component (YUV/RGB).

The digital encoder can handle interlaced mode in all standards. ITU-T 601 aspect ratio displays can be supported in all standards. The digital encoder performs closed-caption, CGMS, WSS, Teletext and VPS encoding and allows Macrovision[™] 7.01/ 6.1 copy protection.

One integrated quad-DAC provides four analog TV outputs, on which it is possible to output either of the following:

- CVBS + RGB,
- CVBS + YUV,
- S-VHS (Y/C) + CVBS1 + CVBS2.

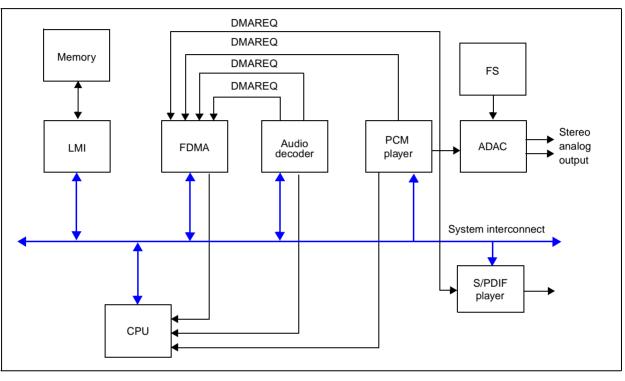

3.9 Audio subsystem

The audio subsystem illustrated in Figure 6 supports the following features:

- audio decoding of MPEG-1 layers I and II,
- simultaneous MPEG-1 audio decoding and the compressed output of Dolby streams on the S/PDIF,
- audio sample rates of 32 kHz, 44.1 kHz and 48 kHz.

Figure 6: Audio subsystem

The audio subsystem consists of the following units:

- audio decoder,
- S/PDIF player,
- PCM player,
- integrated 24-bit stereo audio DAC system,
- audio/digital frequency synthesizer (generates the PCM and sample rate clocks).

3.10 Central DMA controller

The STx5119 has a multichannel, burst-capable direct memory access controller that supports the following:

- fast 2D unaligned memory to memory transfers of graphics and stills,
- real time stream transfers to and from memory with or without pacing. These channels are suitable for transfers with external peripherals and for audio and video stream transfers within the STx5119.

3.11 Internal peripherals

The STx5119 has many dedicated internal peripherals for digital TV receiver applications, including:

- two ASCs (UARTs), that are generally used as smartcard controllers or for modem application,
- two SSCs for I²C master/slave interfaces, with SPI support,
- four GPIO ports,
- Infrared blaster/decoder interface module,
- DVB-CI support,
- fully integrated digital VCXO,
- interrupt level controller,
- low-power RTC watchdog controller,
- DCU toolset support,
- JTAG/TAP interface.

3.12 Clock generation

All system clocks are generated using the clock generator block. This contains two high-frequency PLLs that are divided down to produce a series of phase-related programmable clock channels.

The STx5119 has a clock master. The Flash clock output may be phase aligned to optimize the external bus performance of the FMI.

VCXO functionality has been integrated using a special purpose frequency synthesizer, thus removing the need for an external varactor diode or VCXO module.

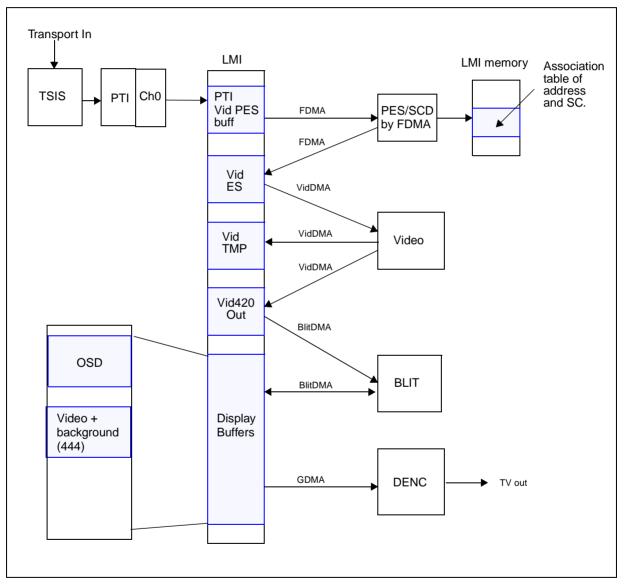

4 Dataflow

This chapter describes the system dataflow for AV reproduction from the front-end compressed stream, through the AV decoders and various buffers to the final AV presentation.

In the following dataflow, the programmable transport interface (PTI) performs the transport stream deMUX. The channel 0 DMA generates audio and video circular buffers in main memory.

4.1 Video decode flow

Figure 7: Video decode flow

The PTI channel 0 circular video buffer is accessed by the FDMA which is a linear linked list machine. The synchronization is described in the following paragraph.

The host CPU is interrupted by a programmed timer event from system services, for example every 10 ms. The interrupt routine reads the ch0 write pointer from the PTI; using this, and the previous write pointer, a single pass linear access is activated using a dedicated process (PPSCD) running on the FDMA (with hardware assist) to perform PES parsing and start code detect.

The FDMA PPSCD process generates an elementary stream (ES) buffer in main memory and an association table which can be placed in external memory or local SRAM.

Each entry of the PPSCD table contains the following information:

- start code value,
- PTS if present,
- start code offset in PES buffer,
- start code address in the ES buffer.

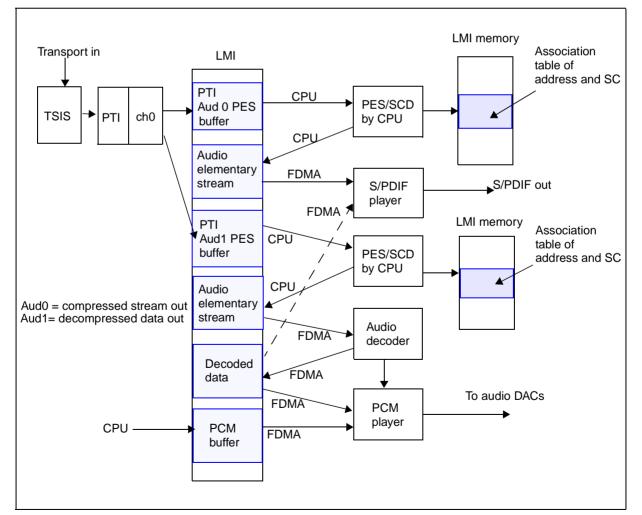

This table is accessed by the video driver running on the host CPU. The ES video buffer is accessed directly using the linear DMA engine inside the video decoder. This block generates several intermediate buffers during the prediction and reconstruction phases of decode before generating a final video buffer in YCbCr 4:2:0 format.

The video buffer is read directly by the blitter which performs multiple passes to format convert and blend the video buffer with a background and OSD overlay, before rendering a final display buffer in YCbCr 4:2:2 format.

The picture composed by the blitter is always frame based. The final presentation buffer is read by the GDMA which drives the digital encoder to produce composite video output. The GDMA should be programmed to access the presentation buffer field based.

4.2 Standard audio decode flow

Figure 8: Standard audio decode flow

Confidential

The PTI fills the circular audio PES buffers in the external memory. The PES parsing and start code detection is performed by the CPU or by FDMA. The PES parsing and start code detection process is the same as the process described in the video decode data flow.

The elementary stream, corresponding to the bypass (Dolby stream), is moved to the S/PDIF player by the FDMA. The FDMA performs appropriate formatting for the S/PDIF player. The S/PDIF player outputs the data on the S/PDIF output.

The audio elementary stream to be decoded is moved to the audio decoder. The decoded data is then read by the FDMA and appropriately buffered in the external memory. The decoded PCM stream is then fed to the PCM player. The output of the PCM player drives the audio DACs.

The FDMA can also move the decoded audio, which is buffered external to the audio decoder, to the S/PDIF player after appropriate formatting. The formatting consists of the addition of channel status, user data and validity flag.

The CPU generates a PCM buffer which can be used to generate the beep tones or sync noise. The contents of the buffer are moved to the PCM player by the FDMA. The quad frequency synthesizer provides the PCM and the S/PDIF clocks.

4.3 Real-time traffic

4.3.1 Paced external

Cable front-end using the STB0294B device

The STx5119 accesses the STB0294B via a target interface connected to the FMI. Datagrams may be moved to and from internal buffering within the STB0294B using the FDMA. Flow control is achieved by using standard DMAREQ pacing signals that are routed to the FDMA within the STx5119.

Note: The STx5119 and FMI external bus is shared with a flash memory.

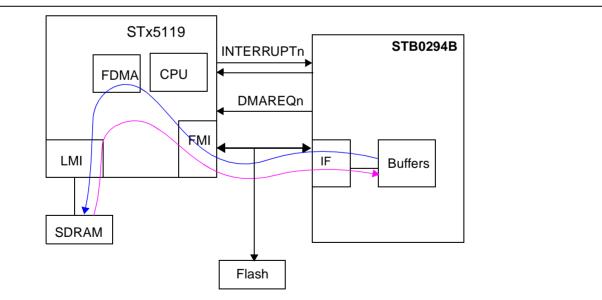

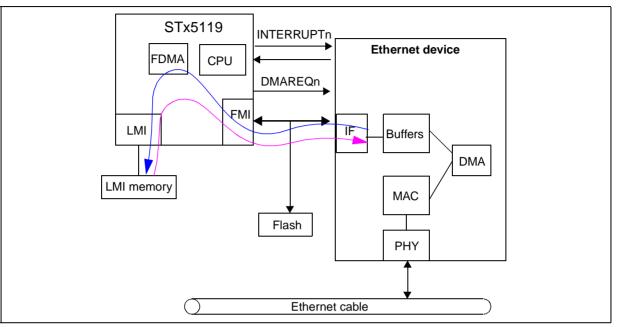

Figure 9: Cable front-end device

Confidential

4.3.2 External ethernet

External ethernet devices are mapped to the FMI in the same way as the STB0294B. The STx5119 FDMA fetches from and writes to buffers in the external ethernet device. A service request is made by asserting an interrupt to the STx5119.

5 Package specifications

The STx5119 is packaged in a 216-pin LQFP-EP (exposed pad) package. Table 2 gives the values of the dimensions marked in Figure 11.

Dimension	Databook (mm)			Drawing (m	Drawing (mm)

Table 2: Package dimensions

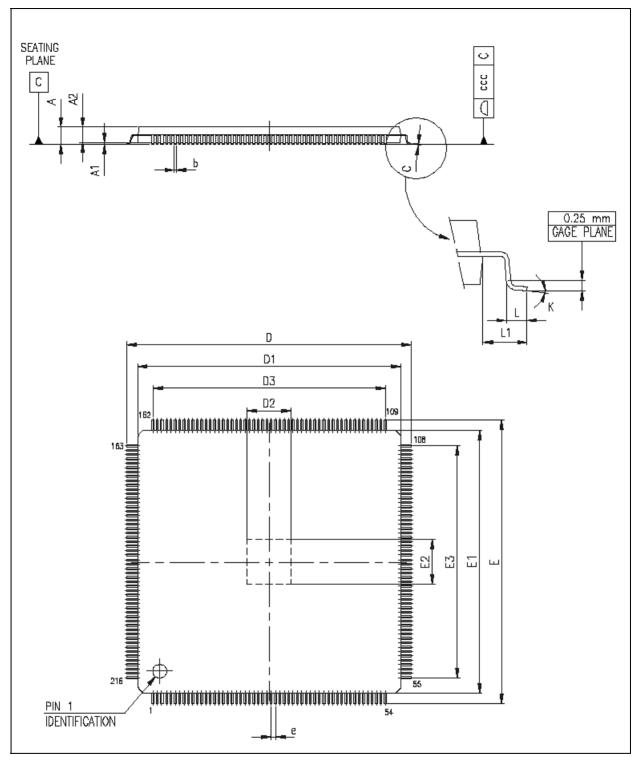

Figure 11: STx5119 LQFP-EP package

5.1 Exposed pad description

The TQFP/LQFP package with exposed pad is made with a deep down set leadframe so that the bottom side of the die paddle is flush with the bottom side of the package and is exposed. This allows the exposed pad to be soldered directly to the PCB and facilitates high heat dissipation. Although direct soldering of the exposed pad to the PCB is the best way to get effective power dissipation, thermal glue can be used as well.

1. ZO is the output pin of oscillator.

All digital pads are 3.3 V capable, selected pads are 5 V tolerant.

Interface	Drive (mA)	5 V tolerant	Pull up/down	Tstate control
SDRAM		No	No	Yes
FMI	4	No	Yes ¹	Yes
Transport	4	Yes (data only)	Yes (data only)	Yes (data only)
Test/Debug	4	Yes (except on TCK)	Yes (except on TCK, TDO)	Yes (except on TCK)
Digital I/O ²	4	Yes	Yes (except PIO3[3:0]) ³	Yes
System	4	Yes (except clock and reset input pins)	Yes (except clock and reset input pins)	No

1. Except FMIADDR22 and FMIDDR23 that have no pull-up/down.

2. PIO3 bit 6 is 3.3 V capable but not 5 V tolerant.

3. Pins PIO3[3:0] (I²C interface) are open-drain and all other digital pads are push pull.

6.2 Alternative functions (mapped to GPIO pins)

To improve flexibility and to allow the STx5119 to fit into different set-top box application architectures, the input and output signals from some of the peripherals and functions are not directly connected to the pins of the device. Instead, they are assigned to the alternative function inputs and outputs of a PIO port bit. This scheme allows the pins to be configured with their default function if the associated input or output is not required in that particular application.

Inputs connected to the alternative function input are permanently connected to the input pin. The output signal from a peripheral is connected when the PIO bit is configured to push-pull function mode.

Figure 13: I/O port pins

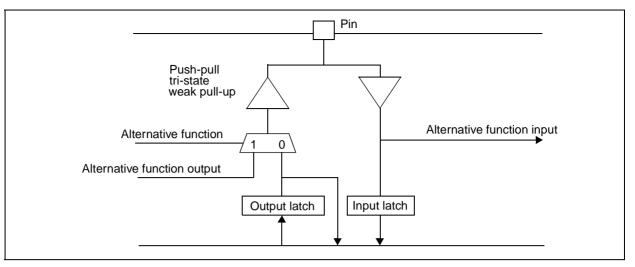

Table 5 to Table 8 show the mapping of the alternative functions. Unless otherwise stated, the default after reset for alternative functions is the PIO port or pin function.

The alternative configurations are set using the PIOn_ALTFOP_MUX_SEL_BUS [7:0] bits in the CONFIG_CTRL_F, and CONFIG_CTRL_G top-level configuration registers.

Note: Pins for FMIADDR22 and FMIADDR23 should be pulled up with an external resistor for correct operation of the device.

7.5 SDRAM interface for LMI

The LMI supports 64-,128-, 256- or 512-Mbit memory configurations, organized as 2 Mbytes x 4 banks x 16 bits. The 64-Mbit configuration uses all signals on the interface, with the LMI's LMIADDR[10:0] pins being directly connected to SDRAM's A[10:0]. For other configurations LMIADDR[12:11] are also connected to the SDRAM's A12 and A11 bits, as appropriate. Only one device can be connected to a board, operating in LVTTL weak mode.

Pin	Assignment	I/O	Description
201	LMIDATA15	I/O	Bidirectional data

7.8 Peripherals

7.8.1 Asynchronous serial controller (ASC)

There are two ASCs available. The ASC0 is smartcard capable, see Table 19: *Smartcards pin mapping* on page 43 for mapping details.

Table 18: Asynchronous serial controllers pin mapping

Pin	Alternative function	I/O	Description	Usual assignment
Async	chronous serial controller 0			
126	ASC0_NOTOE	0		PIO0[6]
118	ASC0_TXD	0	ASC0 transmit data signal	PIO0[0]
119	ASC0_RXD	I	ASC0 receive data signal	PIO0[1]
122	ASC0_RTS	0	ASC0 request to send signal	PIO0[4]
123	ASC0_CTS	I	ASC0 clear to send signal	PIO0[5]
108	ASC1_TXD	0	ASC1 transmit data signal	PIO2[0]
109	ASC1_RXD	Ι	ASC1 receive data signal	PIO2[1]
110	ASC1_RTS	0	ASC1 request to send signal	PIO2[2]
111	ASC1_CTS	Ι	ASC1 clear to send signal	PIO2[3]

2 Smartcard

Table 19: Smartcards pin mapping

Pin	Alternative function	I/O	Description	Usual assign- ment
	Smartcard 0			
122	SC0_RESET			PIO0[4]
123	SC0_COMD_VCC			PIO0[5]
126	SC0_DIR			PIO0[6]
127	SC0_DETECT			PIO0[7]
118	SC0_DATAOUT		Serial data output	PIO0[0]
119	SC0_DATAIN		Serial data in	PIO0[1]
120	SC0_CG_EXTCLK		External clock	PIO0[2]
121	SC0_CG_CLK		Clock for smartcard from system clock	PIO0[3]
122	SYSRV_SC_RESET_0		Reset to card	PIO0[4]
123	SYSRV_SC_POWER_0		Smartcard power	PIO0[5]
127	SYSRV_SC_DETECT_0		Smartcard detection	PIO0[7]
118	SC0_DATAINOUT			PIO0[0]
121	SC0_FSCLK0		Clock for smartcard from smartcard FS	PIO0[3]

7.8.3 Synchronous serial controllers (SSC0 and SSC1)

There are two synchronous serial controllers: SSC0 and SSC1.

For I^2C operation, only two wires are required for half duplex operation. The SSC1 can be an I^2C master or slave because the pin MTSR_DINOUT is connected internally to the MTSR or MRST data in and data out ports of the SSC under software configuration control.

For SPI operation, three wires are required for full duplex operation. Hence MTSR data and MRST data signals are on separate pins.

The SSC0 is available for use in I^2C mode only, as its MRST and MTSR pins are not available separately.

Pin	Alternative function	I/O	Description	Usual assignment
	Synchronous serial control	ler 0		
5	SSC0_SCLKINOUT	0	Serial clock in	PIO3[1]
4	SSC0_MTSR_DINOUT	I	Serial data input for SSC0: master transmit, slave receive	PIO3[0]
	Synchronous serial control	ler 1		
119	SSC1_MRST_DINOUT	0	Serial data for SSC1: master receive, slave transmit	PIO0[1]
120, 7	SSC1_SCLKINOUT	0	Serial clock in	PIO0[2], PIO3[3]
126, 6	SSC1_MTSR_DINOUT	Ι	Serial data input for SSC1: master transmit, slave receive	PIO0[6], PIO3[2]

Programmable I/O

Table 21: Programmable I/O pins

Pin	Assignment	I/O	Description
127	POI0[7]	I/O	PIO port 0

Confidential

47/543

Note: If there is a lot of noise on the clock line a capacitor in the range of 10 to 100 pF can be fitted between TCK and ground near the target STx5119.

8 Configuration registers

The following functions are enabled and disabled using the configuration registers:

- alternative assignments on pins,
- switching of S/PDIF output between the audio decoder and the S/PDIF player,
- video DAC control,
- audio DAC control,
- interrupt direction,
- EMI pull-ups,
- smartcard clock selection,
- DMAREQ direction and polarity.

Addresses are provided as either the *ICMonitorBaseAddress* or the *ICControlBaseAddress* + offset.

The *ICMonitorBaseAddress* is: 0x2040 2000.

The *ICControlBaseAddress* is: 0x2030 3000.

10 Interrupt system

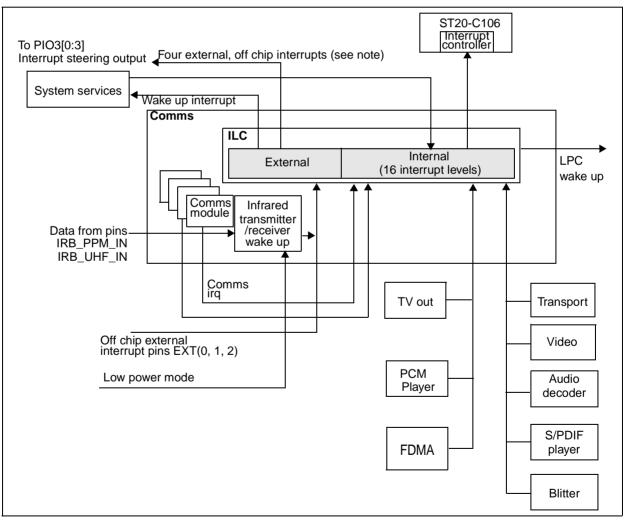

10.1 Overview

The interrupt system allows an on-chip module, or external interrupt pin, to interrupt an active process so that an interrupt handling process can be run. Interrupts are signalled by one of the following:

- a signal on an external interrupt pin,
- a signal from an internal peripheral or subsystem,
- software asserting an interrupt in the pending register.

Interrupts are implemented by an on-chip interrupt controller (see Section 10.2: Interrupt controller on page 57) and an on-chip interrupt level controller (ILC) (see Section 10.3: Interrupt level controller on page 60). The ILC multiplexes the 44 incoming interrupt sources onto the 20 programmable ILC interrupt level inputs (16 to the CPU and 4 available externally). Multiplexing is controlled by software. An overview of the interrupt system is shown in Figure 15.

Figure 15: Interrupt network

Pins INTERRUPT[3:0] can be connected to both the interrupt steering outputs or the four external interrupt inputs.

Note: The four remote OFF chip interrupts are routed from the ILC to PIO3 pads, two of which are routed are as DMAREQ, PIO3[0,1] and two are routed as external interrupts EXT_INT_OUT, PIO3[2:3].

10.2 Interrupt controller

The interrupt controller supports 16 prioritized interrupts as inputs, and manages the pending interrupts. This allows nested pre-emptive interrupts for real-time system design. Interrupt level 15 has the highest priority and interrupt level 0 has the lowest.

All interrupts have a higher priority than the low priority process queue. Each interrupt can be programmed to be at a lower or higher priority than the high priority process queue by writing to the priority bit in the INC_HANDLERWPTR registers. Interrupts which are specified as higher priority must be contiguous from the highest numbered interrupt downwards. For example, if eight interrupts are programmed as high priority and eight as low, then the higher priority interrupts must be set to interrupt [15:8] and the lower priority interrupts to interrupt [7:0].

Each of the 16 interrupt levels of the interrupt controller can be programmed with an interrupt trigger mode, using the INC_TRIGGERMODE register. The trigger mode can be set to be high or low level, rising edge, falling edge or any edge sensitive. All on-chip module interrupt sources produce active high level interrupt signals. Therefore the interrupt level for these interrupt sources must be programmed with a high level trigger mode.

Each of the 16 interrupt levels can be programmed to be enabled or disabled by the INC_MASK register. The default state of INC_MASK is that all interrupt levels are disabled. A corresponding level bit is set in the INC_PENDING register if the interrupt signal from the interrupt level controller matches the level trigger condition. If this is the highest priority bit set in the INC_PENDING register, the CPU then executes the interrupt handler associated with that level by the INC_HANDLERWPTR register and the INC_PENDING bit is then reset. If the level bit set in the INC_PENDING register is not the highest priority bit set, then the bit remains set until it is the highest priority level bit, then the CPU executes the associated interrupt handler for that level. The CPU only executes the interrupt handler and then clear the INC_PENDING register bit if it is enabled in the INC_MASK register. Software can write to the INC_PENDING register to generate a software interrupt on any of the 16 interrupt levels.

Programming the INC_MASK, INC_PENDING and INC_TRIGGERMODE registers is supported by the operating system run time library functions of OS20.

The interrupt controller also contains an INC_EXEC register. This is used by the interrupt controller logic to keep a record of which interrupt level handler is currently executing on the CPU (or was previously executing before being preempted by a high priority process, for low priority interrupts) and which levels have been preempted by higher priority interrupt levels. This register can be read by user software, if required, but the register must never be written to as its behavior is undefined.

Figure 16: Interrupt priority

4	Interrupt 15
	Interrupt 0 when priority bit set to 0
Increasing pre-emption	High priority
	Interrupt 15 when priority bit set to 1
	Interrupt 0 when priority bit set to 1
	Low priority

10.2.1 Interrupt vector table

The interrupt controller contains a table of pointers to interrupt handlers. There are 16 interrupt handlers, each controlled by a work space register INC_HANDLERWPTR 0 to 15. The table of pointer values contains a work space pointer for each interrupt level.

The INC_HANDLERWPTR registers access the code, data and interrupt save area of the interrupt handler. The position of the INC_HANDLERWPTR register in the interrupt table sets the priority of the interrupt.

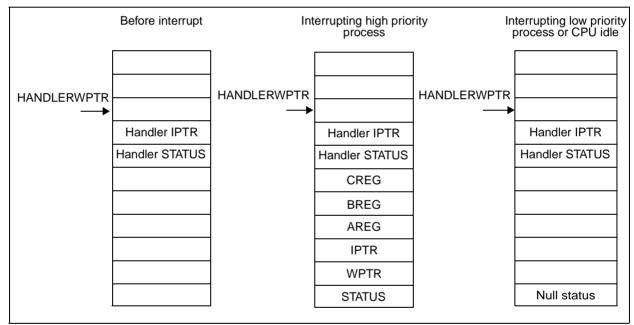

The operating system run time library (OS20) supports the setting and programming of the vector table.

10.2.2 Interrupt handlers

The CPU can receive an interrupt request from the interrupt controller at any interruptible point in its execution and immediately acknowledges the request.

In response to receiving an interrupt, the CPU performs a procedure call to the process in the vector table. The state of the interrupted process is stored in the work space of the interrupt handler as shown in Figure 17. Each interrupt level has its own work space.

The interrupt routine is initialized with space below HANDLERWPTR. The IPTR and STATUS word for the routine are stored there permanently. This should be programmed before the HANDLERWPTR is written into the vector table.

The behavior of the interrupt differs depending on the priority of the CPU and the interrupt, when the interrupt occurs. If an interrupt occurs when the CPU is running at high priority, and the interrupt is set at a higher priority than the high priority process queue, the CPU saves the current process state (AREG, BREG, CREG, WPTR, IPTR and STATUS) into the work space of the interrupt handler. The value of HANDLERWPTR, which is stored in the interrupt controller, points to the top of this work space. The values of IPTR and STATUS to be used by the interrupt handler are loaded from this work space and starts executing the handler. The value of WPTR is then set to the bottom of this save area.

If an interrupt occurs when the CPU is running at high priority, and the interrupt is set at a lower priority than the high priority process queue, no action is taken and the interrupt waits in a queue until the high priority process queue is empty (see Section 10.2.4: *Pre-emption and interrupt priority on page 59*).

Interrupts always take priority over low priority processes. If a high priority interrupt occurs when the CPU is idle or running at low priority, the STATUS is saved. This indicates that no valid process is running (null status). The state of the interrupted low priority processes is stored in shadow registers. This state can be accessed via the **Idshadow** (load shadow registers) and **stshadow** (store shadow registers) instructions. The interrupt handler is then run at high priority.

When the CPU runs at low priority and the interrupt has lower priority than a high priority process, the CPU saves the current process state (AREG, BREG, CREG, WPTR, IPTR and STATUS) into the work space of the interrupt handler. The value HANDLERWPTR, which is stored in the interrupt controller, points to the top of this work space. The values of IPTR and STATUS to be used by the interrupt handler are loaded from this work space and starts executing the handler. The value of WPTR is then set to the bottom of this save area.

When the interrupt routine has completed it must adjust WPTR to the value at the start of the handler code and then execute the **iret** (interrupt return) instruction. This restores the interrupted state from the interrupt handler structure and signals to the interrupt controller that the interrupt has completed. The processor then continues from where it was before being interrupted.

10.2.3 Interrupt latency

The interrupt latency depends on the type of data being accessed, and the position in memory of the interrupt handler and the interrupted process. This allows a trade off between fast internal SRAM memory and interrupt latency.

10.2.4 Pre-emption and interrupt priority

Each interrupt channel has an implied priority fixed by its place in the interrupt vector table. All interrupts cause scheduled processes of any priority to be suspended and the interrupt handler started. Once an interrupt has been sent from the controller to the CPU the controller keeps a record of the current executing interrupt priority in the INC_EXEC register. This is only cleared when the interrupt handler executes a return from interrupt (**iret**) instruction. Interrupts of a lower priority arriving are blocked by the interrupt controller until the interrupt priority is low enough for the routine to execute. An interrupt of a higher priority than the currently executing handler is passed to the CPU and causes the current handler to be suspended until the higher priority interrupt is serviced. In this way, interrupts can be nested and a higher priority interrupt always preempts a lower priority one.

Note: Deep nesting and the placing of frequent interrupts at high priority can result in systems where low priority interrupts are never serviced or CPU time is consumed in nesting interrupt priorities instead of executing the interrupt handlers.

10.2.5 Restrictions on interrupt handlers

For optimum interrupt handling, the following restrictions are placed on interrupt handlers.

- Interrupt handlers must not deschedule.
- Interrupt handlers must not execute communication instructions. (However, they may communicate with other processes through shared variables using the semaphore signal to synchronize.)
- Interrupt handlers must not perform CPU 2D block move instructions.
 A workaround is to store the state of the shadow registers used by the 2D block move instruction into memory, with the **stshadow** instruction. The state must be restored after the 2D block move instruction by using the **Idshadow** instruction.
- Interrupt handlers must not cause program traps. (However, they may be trapped by a scheduler trap.)

10.3 Interrupt level controller

The interrupt level controller multiplexes 64 internal and 8 external interrupt source signals on to the 16 interrupt level inputs of the interrupt controller. In this way, it gives programmable control of the priority of the interrupt sources and extends the number of possible interrupts. In addition, interrupt steering is provided to allow routing of a further four interrupts off chip, any interrupt source may be mapped on to any of the four outputs.

The incoming interrupt signals can be generated by on-chip subsystems or received from external pins. Table 27 on page 61 assigns each of the interrupt sources to a number n from 0 to 63. Software assigns a signal n to one of the 16 interrupt levels by writing the priority of the required input in the register ILC_PRIORITY. Each of the 44 interrupt sources in the interrupt level controller can be selectively enabled or disabled at source, by writing to the ILC_ENABLE register. This is in addition to the individual masking of the 16 levels in the interrupt controller. This disables the interrupt source from generating an interrupt, without disabling all other interrupt sources mapped on to that interrupt level. This would be the case if the INC_MASK register in the interrupt controller was used.

All internal interrupts are assumed to be level sensitive and active high.

Each external interrupt source can be used to trigger an interrupt and can be programmed to trigger on rising or falling (or either) edges, or on the high or low logic level of the incoming interrupt source signal. This is controlled by writing to the ILC_MODE registers.

The default state of the interrupt level controller trigger mode registers is no trigger, therefore, these registers need to be programmed if external interrupts are to be enabled. The default state of the enable registers is low, therefore these registers need to be programmed before internal interrupts can be serviced.

When setting trigger modes in the interrupt level controller, the corresponding trigger mode for the interrupt level in the interrupt controller that the source(s) are mapped to, must be programmed to high level. Otherwise, the trigger mode in the interrupt controller and the interrupt level controller may conflict. The ILC_INPUT_INTERRUPT register has the same function as in the STi5500, STi5505, STi5508, STi5518 and can be used to indicate the current logic state of all the interrupt sources. This register is just a buffered version of the interrupt source signals before the trigger mode detection stage. ILC_INPUT_INTERRUPT does not latch the signal, as the ILC_STATUS register does, for interrupt sources defined with an edge sensitive trigger mode. The ILC_STATUS register is more useful because of this feature, as it can be read by the interrupt handler software routine to determine which interrupt sources have triggered.

For example, if the interrupt source is external and provides a pulse, the interrupt level controller would have the interrupt source trigger mode set to be rising edge. On a rising edge the corresponding bit in the ILC_STATUS register would be set high and would remain set until explicitly cleared by the interrupt handler routine writing to the corresponding bit in the ILC_CLEAR_STATUS register. However if the pulse was short, by the time the interrupt handler was executed and had read the ILC_INPUT_INTERRUPT register, the pulse may have returned to a logic low and the bit would be read as zero. Thus the cause of interrupt could not be determined if more than one interrupt source had been multiplexed on to the interrupt level.

So now, using the ILC_STATUS register, it is possible to multiplex interrupt sources of different types, including edge sensitive, on to the same interrupt level in the interrupt controller.

The STx5119 interrupt level controller also has two registers mapped into its register address space, that have no connection with normal interrupt operation. These registers control the wake up of the CPU by an external interrupt pin, when it has been put into low power mode, by the low power controller module. The register ILC_WAKEUP_ACTIVE_LEVEL controls whether the four external interrupt pins are active high or low, to wake up the CPU from low power mode. The setting of this register has no effect on the triggering of the external interrupt pins in the interrupt level controller. The register ILC_WAKEUP_ENABLE is a mask register to enable or disable the external interrupt pins from waking up the CPU from low power mode. Again, this has no effect on the masking of these interrupts in the interrupt level controller.

10.4 Interrupt assignments

All interrupts are active high. Interrupts from the internal peripherals and external pins are assigned as in Table 27.

	Reserved CLR CLR CLR CLR CLR CLR CLR CLR CLR CLR
Address:	IntControllerBaseAddress + 0x048
Туре:	Write only
Description:	When set, bits 0 to 15 of this register clear the corresponding interrupt exec bit (INTEX) in register INC_EXEC. There is one bit for each of the 16 interrupt levels, where bit 0 corresponds to bit INTEX0. Bit 16 of this register clears all of the bits of the INC_EXEC register.
Note:	This register must not be used as its operation is undefined.

INC_CLEAR_MASK Clear a bit of the interrupt enable mask

Reserved A CLR	CLR CLR CLR CLR CLR CLR CLR CLR CLR

 Address:
 IntControllerBaseAddress + 0x028

 Type:
 Write only

 Description:
 When set, bits 0 to 15 of this register clear the corresponding interrupt enable bit (INTEN) in register INC_MASK. There is one bit for each of the 16 interrupt levels, where bit 0 corresponds to bit INTEN0. Bit 16 of this register clears all of the bits of the INC_MASK register.

INC CLEAR PENDING Clear a bit of the pending register

31 30 29 28	28 26 25 24 23 22 21 20 19 18 17 16	15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
	Reserved	CLR															
Address:	IntControllerBaseAddress + 0x018																
Type:	Write only																
Description:													he				

INC EXEC

Interrupts executing

15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
INTEX15	INTEX14	INTEX13	INTEX12	INTEX11	INTEX10	INTEX9	INTEX8	INTEX7	INTEX6	INTEX5	INTEX4	INTEX3	INTEX2	INTEX1	INTEX0
Addre	SS:	IntC	ontroll	erBase	Addre	ess + 0	x040								

Type: Read/write Reset: 0

Description: This register records whether interrupt levels 0 to15 are currently executing and preempting interrupts. The bit is set when the CPU starts running code for that interrupt, where INTEX0 corresponds to interrupt level 0. The highest priority interrupt bit is reset once the interrupt handler executes a return from interrupt instruction (iret). This register is specified as being read/write, but users should not attempt to write to this register, as the device operation is undefined.

INC_GLOBAL_MASK **Enable all interrupts**

15	14	13	12	11	10	9	8	7	6	5	4	3	2	1	0
							Reserved								GLOBAL_MASK

Address: IntControllerBaseAddress + 0x030

Type: Read/write 0

Reset:

This register has similar functionality to the INC_MASK register, except that it has a Description: single bit which masks all of the interrupts. Writing to GLOBAL_MASK has no effect on the contents of the INC_MASK register.

[15:1] Reserved

- [0] GLOBAL_MASK
 - 1: global mask enabled
 - 0: global mask disabled.

Interrupt handler work space pointer

Address: IntControllerBaseAddress + 0x100 to 0x13C

Type: Read/write

Undefined Reset:

Description:

This register points to the work space of the corresponding interrupt handler (HANDLERWPTR0 corresponds to interrupt level 0). The base of the work space is 32-bit word aligned, so the two least significant bits of the 32-bit address are always zero, and are not held. Each register contains a priority bit P which determines whether the interrupt is at a higher or lower priority than the high priority process queue. Before the interrupt is enabled by writing 1 in the INC MASK register, the software must ensure that there is a valid HANDLERWPTRn in the register.

[31:2] HANDLERWPTRn[31:2]

The 30 most significant bits of the address of the work space of the interrupt handler.

[1] Reserved

[0] **P**

Sets the priority of the interrupt. If this bit is set to 0, the interrupt is a higher priority than the high priority process queue; if this bit is 1, the interrupt is a lower priority than the high priority process queue. 0: High priority

1: Low priority

INC_MASK

Interrupt enable mask

31 30 29 28 28 26 25 24 23 22 21 20 19 18 17 16 15 14 13 12 11 10 9 8 7 6 5 4 3 2 1 0

Address: Type:	IntControllerBaseAddress + 0x020 Read/write																

Reset:

Description: This register selectively enables or disables interrupts from the interrupt level controller, connected to each of the 16 interrupt levels. The global interrupt disable bit, disables all interrupt levels, whatever the state of the individual interrupt mask bits.

The INC_PENDING register contains a pending flag for each interrupt level. The INC_MASK register masks the INC_PENDING register to control what interrupts the CPU, while continually monitoring interrupts.

On start up, INC_MASK is initialized to zeros so all interrupts are disabled both globally and individually. When 1 is written to the GLOEN bit, the individual interrupt channels are still disabled. To enable an interrupt channel, 1 must also be written to the corresponding INTEN bit.

[31:16] Reserved

0

[15:0] INTEN[15:0]

1: Interrupt enabled

0: Interrupt disabled.

INC_MASK is mapped on to registers INC_SET_MASK and INC_CLEAR_MASK so that bits can be set or cleared individually.

The mode register is set to 0x00 on reset.

12 Memory system

The STx5119 has a fully unified memory system.

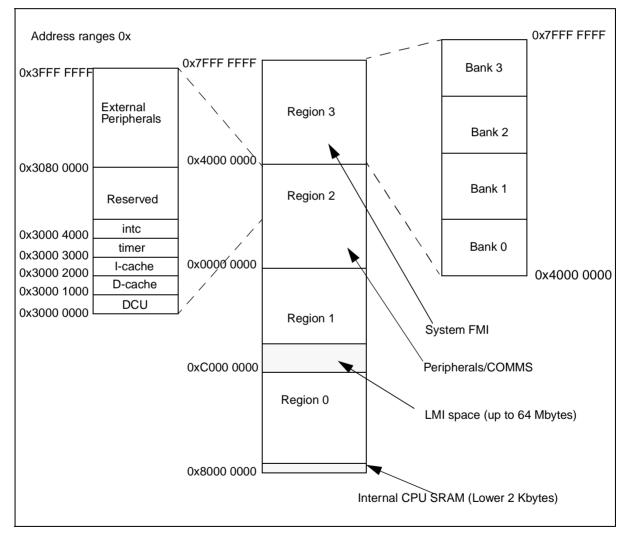

12.1 Memory map

The memory space is divided into four regions:

- region 0: addresses which map onto the C106 embedded SRAM,
- region 1: addresses which map onto the off-chip SDRAM connected to the LMI,
- region 2: addresses which map onto the on-chip peripheral configuration registers,
- region 3: addresses which map onto the flash and peripheral memory interface (FMI).

Figure 18 gives the top level address map breakdown.

Figure 18: Memory map

Confidential

Region 0 is decoded inside the C106 so CPU accesses to that region are not passed out to the STBus. For that reason region 0 contains only the CPU SRAM. See Table 29.

Address range From To		Size	Sector	Pogion type	Subragion type

0x0000 0000	0x201F FFFF	514 Mbytes			Reserved

1. Not accessible by external peripherals, Visible only to CPU. Reserved for external DMA

2. To be decoded on to the same port as FMI

Note: Spaces that are reserved, allow accesses but return unknown data. Reserved spaces must not be programmed as this causes unpredictable behavior.

12.2 CPU cache

There are 4 Kbytes of instruction cache and 4 Kbytes data cache in the STx5119 core. Instruction cache can be accessed only by the CPU fetch unit, and data cache can be accessed only by the CPU execution unit and diagnostic controller unit (DCU).

The caches are direct mapped with write back and are arranged as 256 lines of 16 bytes each. Refill/write back operations always utilise a 16-byte LD/ST access across the interconnect. Selective parts of memory may be configured as cacheable as shown in Figure 19, and all non cacheable requests are arbitrated with the refill/write back stream and compete for the interconnect.

Figure 19:	Cacheability
------------	--------------

0x7FFF FFFF	Dstream	Istream		T
0.4000 0000	Configurable cache	Configurable cache	Region 3	
0x4000 0000	Non-cacheable	Non-cacheable	Region 2	
0x3000 0000	Configurable cache	Configurable cache	Region 1	
0xC000 0000	Internal SRAM	Internal SRAM	Region 0	
0x8000 0000				l

Instruction code may be cached in regions 1 and 3 allowing code to be placed in either the shared memory (LMI space) or FMI space.

The STx5119 has 2 Kbytes of SRAM, this may be accessed by the CPU/DCU. The SRAM cannot be accessed from other STx5119 subsystems outside the core.

CACHE_

13 Cache registers

Register addresses are provided as *CacheBaseAddress* + offset, where *CacheBaseAddress* is either *DCacheBaseAddress* or *ICacheBaseAddress*.

The DCacheBaseAddress is:

14 Local memory interface (LMI)

14.1 Introduction

The local memory interface (LMI) provides the interface between the STBus and the external main memory SDRAM.

The SDRAM controller comprises:

- 16-bit external bus width,
- a single quad bank SRD SDRAM device,
- SDRAM technology: 64-Mbit, 128-Mbit, 256-Mbit, 512-Mbit (main memory size from 8-Mbytes to 64-Mbytes).

14.2 STBus interface

The functionality of the STBus interface is described in the following subsections.

14.2.1 STBus port

The STBus port is divided into one register block and *n* number of data blocks. Each data block is 16 Mbytes in size. The address range of the LMI is defined between the memory base address (0xC000 0000) and the register base address (0xE000 0000).

Data blocks populate starting from 0xC000 0000 inclusive. The upper boundary address of data blocks is defined by the UBA field of the LMI_SDRA[0:1] register (the SDRAM array attribute register's upper bound address). See Section 14.3.1: *Main memory configuration* on page 86)

The control populate starts from 0xE000 0000 inclusive to 0xE000 0050. Table 31 shows the LMI address space organization in the STx5119.

	LMI registers	LMI data blocks				
Lowest address	0xE000 0000	0xC000 0000				
Highest address	0xE000 0050	UBA				

Table 31: LMI address space for the STx5119

When the LMI is active, memory accesses from the STBus to the data blocks cause accesses to be made on the external memory bus. Each external memory access consists of a number of phases, each representing an action performed on the external memory bus. The behavior of the external pins of the LMI can be programmed to allow the LMI to drive the external memory bus in an appropriate way for different SDRAM parts as shown in Table 32 and Table 33.

Table 32: SDRAM output impedance setting

LMI_CLK_OFFSET_CTRL[15:14]	Output buffer impedance range
00	25 Ω
01	40 Ω
10	55 Ω
11	70 Ω (default)

LMI_CLK_OFFSET_CTRL[17:16]	MODE =1 2.5 V series terminated configuration
00	5 pF
01	15 pF (default)
10	25 pF
11	35 pF

14.2.2 Coherency

The memory of the LMI is coherent as viewed from the STBus. All requests are processed sequentially on the local memory interface in the order of the receipt of those requests by LMI. However, the system can decouple the generation of response packets from the actual external memory bus accesses. For store transactions, the corresponding store response packets may not be returned to the initiator on the STBus until the write operations are actually completed on the SDRAM interface. Since the local system is the sole owner of the external main memory and all the requests to the same address are processed in order (as they are received from the STBus interface) on the SDRAM interface, memory coherency is achieved.

A swap packet comes with store data. When processing a swap request, the LMI initiates a read transaction on the SDRAM interface. Once the data is received by the SDRAM controller, a write command is issued.

4.3 SDRAM interface

Confidential

The LMI's SDRAM controller supports one SDRAM device. The functionality of the SDRAM interface is described in the following subsections.

14.3.1 Main memory configuration

The LMI supports a single memory device which is 16 bits wide. The population on the array ranges from 16 Mbytes to 64 Mbytes.

The memory location is placed in the UBA field in the LMI_SDRA0 register. NOT_LMICS is asserted if the STBus request access to the LMI's data block and the request address [31:21] is less than UBA in LMI_SDRA0.

Note: The LMI_SDRA0 and LMI_SDRA1 registers must contain the same values.

14.3.2 SDRAM interface pins

The external pins are described in Table 34.

Name	I/O	Size	Description
LMIMCLKOUT	Output	1	SDRAM clock output
NOT_LMICLKOUT	Output	1	NOT_LMICLKOUT are differential clock outputs to SDRAM.
LMICLKEN	Output	1	Clock enable Activates the clock signal when high and deactivates when low By deactivating the clock, LMICLKEN low initiates the power-down mode, self-refresh mode or suspend mode.
NOT_LMICS	Output	1	Chip select Perform the function of selecting the particular SDRAM components during the active state

Table 34: SDRAM interface pins

Name	I/O	Size	Description
LMIRDNOTWR	Output	1	Write enable signal WE asserted during writes to SDRAM
LMIADDR[12:0]	Output	13	Row and column address
LMIBA[1:0]	Output	2	Bank address
LMIDATA[15:0]	I/O	16	Memory data
LMIDQS[1:0]	I/O	2	Input/output data strobe These pins provide the read and write data strobe signal to/from the receiver circuit of DRAM controller. LMI drives LMIDQS pins in write (store) cycles, while SDRAM drives it in read (load) cycles.
LMIDQM[1:0]	Output	2	Input/output data mask These pins act as byte enables during write cycles.
NOT_LMIRAS	Output	1	Row address strobe The NOT_LMIRAS signal generates encoded SDRAM commands.
NOT_LMICAS	Output	1	Column address strobe The NOT_LMICAS signal generates encoded SDRAM commands.
LMIVREF	Input	1	Input reference voltage

Table 34: SDRAM interface pins

14.3.3 SDRAM devices

fields of LMI SDRA[0:1] registers.

The LMI splits the physical memory address into banks, row and column addresses. The LMI contains 13 external address pins. LMIBA[1:0] specifies which bank, while LMIADDR[12:0] indicates row and column addresses in each bank. The row address selects a page in an SDRAM. The column address selects a datum in a row. The LMI supports memories where row addresses are up to 13 bits.

Table 35 summarizes the SDRAM devices which are used to construct the memory subsystem. They also illustrate LMIADDR pin MUXing against the SDRAM address split. The LMI's LMIADDR[12:0] pins are directly connected to SDRAM's A[12:0]. The address split column in the table specifies the row and column address split within a given bank.

The mapping of BA0 and BA1 (bank select address bits) described in Table 35 on page 87 can be bypassed enabling the bank remapping feature (see the ENABLE BA0 and ENABLE BA1

Note:

14.3.4 Initializing SDRAM devices

An initialization sequence to an SDRAM device must be done after power-on reset by the driver software. The operating system bootup code or driver software to initialize SDRAM should not read or write SDRAM before completion of the initialization.

- The system provides four power in certain sequence. VDD first, VDDQ next then VREF and VTT. VTT is not provided to the LMI. It is externally connected to DQ, DQS and other pins through a series of termination registers. This is required to prevent latch-up in SDRAM devices. LMI should be able to support this power-up sequence. During and after power-on reset CKE must be kept low.
- 2. After all power supply and reference voltages are stable and the clock is stable a 200 μs pause is necessary.
- 3. CKE should be brought high with the **deselect** command. After this point, unless the LMI sends some command, the LMI has to send the **deselect** command.
- 4. A precharge all (pall) is issued to SDRAM.
- 5. A mode register set (**mrs**) command is issued to program the extended mode register to enable the DLL.
- 6. The **mrs** command is issued to program the mode register (LMI_SDMR), reset the DLL in SDRAM and program the operating parameters, for example burst length and CAS latency.
- 7. A precharge all (pall) is issued to SDRAM.
- 8. Wait ten cycles after the DLL reset and send two **cbr** commands to SDRAM.
- 9. An **mrs** command is issued to de-assert the DLL initialization bit in the mode register. Other programing parameters should be the same as in previous programing. For some memory vendors, this step can be skipped because they support autocleaning of the DLL initialization bit.
- 10. After 200 cycles from DLL reset, external memory becomes accessible.

The LMI's SDRAM controller provides two mechanisms for accomplishing the initialization sequence.

1. nop, pall, ckeh and cbr

The LMI_SCR register's SMS (SDRAM mode select) field is written with appropriate values to prompt the SDRAM controller to start issuing to start issuing one of these commands. For instance, when SMS = 3'b100, it results in a single CBR cycle on the SDRAM interface. When SMS = 3'b011, it results in the CKE signals going high.

2. Setting the SDRAM device's mode register

The SDRAM's mode register needs to be initialized before actual operation. The software (boot code) initiates a write cycle to the LMI_MIM register, and then a write to the LMI_SDMR register in the control block. The SDRAM controller then issues an **mrs** command to all SDRAM devices on array (array [n]).

Example: issuing an mrs command

Software does a dummy write to LMI_SDMR, the physical address and data must be arranged in the following way:

- STBus address = 0xC000 0048,
- STBus data bus [15:0] contains the value to be written to the SDRAM's mode register,
- data[9:0] is copied to MA[9:0], data[15:12] to MA[13:10] and data [11:10] to BA[1:0] when an mrs command is issued to the SDRAM devices.

Software needs to ensure that the SDRAM timing specification (between the **mrs** command and the first operational command) is met. One way to ensure this is to perform several SDRAM control register reads.

Subsequently, SMS in the SCR register is written with 3'b000, the normal SDRAM operation can then be started.

Software must program the LMI_MIM register before writing to LMI_SDMR.

The SDRAM controller supports most SDRAM commands. Table 36 lists all commands supported.

Table 36: SDRAM command truth table

1. AP pin: LMI uses the BY32AP bit in the MIM register to determine if the MA8 pin is used to indicate **pre** and **pall** commands.

The LMI does not support full-page burst operation. The LMI issues a **bst** command to terminate the burst read-only in SDRAM mode.

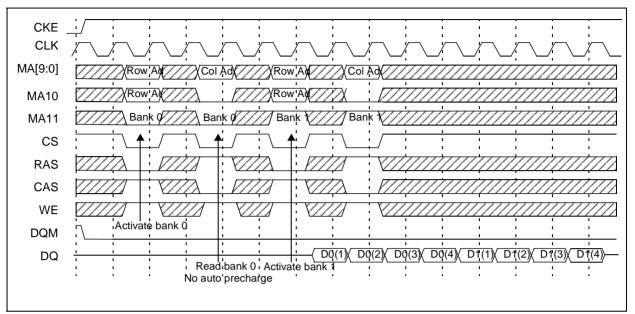

The timing for issuing these commands is governed by the SDRAM timing register LMI_STR. The LMI's SDRAM controller can open up to four pages for each SDRAM array and fully exploit the multibank architecture of modern SDRAM devices by tightly pipelining SDRAM commands. The LMI is capable of detecting multiple consecutive requests to the same SDRAM page. The SDRAM controller may combine same-page requests into a single same-page access, providing that the timing of the requests is suitable.

Note:

Multibank ping-pong transaction

Two bank ping-pong access is illustrated in Figure 20. The peak bandwidth is obtained in this scenario.

When DRAM refresh enable is 1 (DRE in LMI MIM = 1), The LMI can automatically generate refresh cycles. A 12-bit quantity (DRI, DRAM refresh interval in LMI MIM) specifies the number of memory clock cycles between refreshes. Software should program DRI in the inclusive range [128: 4095]. The behavior of the DRAM controller is undefined if the LMI is enabled and if DRI is less than 128.

At the start of a refresh interval, the SDRAM controller loads DRI's 12-bit value into an internal counter. This counter is decremented by 1 in each memory clock cycle. When the counter reaches 0. DRI's value is reloaded into the counter and the next refresh interval is started.

All banks must be closed before refresh operation can be performed. The SDRAM controller issues a precharge all (**pall**) command if there are any open pages. The SDRAM controller then issues an auto refresh command (cbr) after the TRP parameter is satisfied. The next row act command can be issued TRFC clock (SRFC in LMI STR) later.

The SDRAM controller performs one refresh operation for each refresh interval. It attempts to perform **cbr** as soon as possible within the refresh interval. When the counter < 128 and **cbr** is not issued in the current refresh interval the SDRAM controller causes any current SDRAM access to complete in a timely manner by ensuring that the detection of same-page SDRAM access is prevented. Subsequently it performs **pall** and **cbr** commands.

The maximum refresh rate that the LMI can support is one row every 128 clock cycles. At this rate, however, the detection of same-page SDRAM accesses is permanently disabled.

As an example, the hard reset value of DRI is 1,562. For a 100 MHz memory clock, then this allows 1.024 refreshes in less than 16 ms.

Note: On average, the interval between two refreshes is determined by the DRI setting. However the interval between any two successive refreshes could be larger or smaller than DRI by (a page miss 32-byte transfer) clocks.

14.3.7 Power management

The LMI provides one power management mechanism.

When the LMI receives STBY_REQ from the power-down management unit (PMU), the LMI prepares the SDRAM to enter low power state. The sequence of events for both entering and leaving standby mode is described below. To make the correct sequence, cooperation with the software driver is important.

Entering standby

- 1. At first, no initiators should be issuing transaction requests to the LMI. The LMI does not de-assert the grant signal during the standby so it is mandatory not to send any requests during this phase.
- 2. The standby management program should issue a **cbr** command as the last command to LMI.
- 3. The standby management program asserts STBY_REQ to LMI.
- 4. All outstanding transaction requests are serviced.
- 5. The SDRAM controller issues a self-refresh command and lowers LMICLKEN TO SDRAM. The SDRAM autonomously refreshes itself for the duration of the power-down mode.
- LMI asserts STBY_ACK to PMU. The memory clock (MCLKO) can now be stopped. The clock controlling the padlogic FFs can be switched off when STBY_REQ (provided by PMU) and STBY_ACK (provided by the LMI core) are both asserted (STBY_REQ/STBY_ACK has to be combined to act as enable signal of gated clock cell outside the LMI core).
- *Note:* The LMI core switches off both its clocks (memory and bus clocks) under the same conditions (STBY_REQ and STBY_ACK both high).

Leaving standby causes other than power-on reset

- PMU de-asserts STBY_REQ. As an effect of this, the STBus clock and SDRAM clock inside the LMI core resume. The same happens in the padlogic if the same clock gating logic (STBY_REQ/STBY_ACK combined to act as enable of gated clock cell) is implemented outside the LMI core.
- 2. The LMI de-asserts STBY_ACK, and starts to count down from (256 x CST (SCR)) to zero every memory clock cycle.
- 3. When countdown reaches zero, the SDRAM controller asserts the LMICLKEN pin and sends **deselect** commands continuously. SDRAM exits from self-refresh mode.
- 4. The LMI starts to count down from (16 x XSR(STR)) to zero every memory clock cycle. In this period no SDRAM command is sent to the memory.
- 5. For SDRAM, the LMI issues numbers of **cbr** commands defined by the BRFSH field in CSR.

15 Local memory interface (LMI) registers

If the LMI is active, the transactions to the registers are processed only when there are no outstanding data block transactions. While the LMI is processing control block transactions, the SDRAMs are in idle state. After processing control block transactions, the LMI's DRAM controller then continues with its normal behavior which reflects the state of the control registers. The LMI ensures that the change from the original behavior to the subsequent behavior is achieved instantaneously at a boundary between SDRAM commands during the processing of that transaction.

Addresses are provided as the LMIBaseAddress + offset.

The LMIBaseAddress is:

0xE000 0000.

LMI_SDMR[1:0]

SDRAM array mode

	· - ·
Address:	LMIBaseAddress + 0x0048, + 0x0050
Туре:	Write only
Reset:	Undefined
Description:	This register is a write-only virtual register, since physically it is not contained in the processor chip. A write to this virtual register triggers an SDRAM mode register set command to be issued to an SDRAM device. The value on STBus data bus TARGET_1_DATA[9:0] is copied to the MA[9:0] pins, TARGET_1_DATA[11:10] is output to BA[1:0] and TARGET_1_DATA[15:12] is driven

to MA[13:10]. In response to the mode register set command, the SDRAM device then latches MA[11:0] and BA[1:0] into its mode register. A read to this register returns an undefined value.

Please refer to the SDRAM manufacturer's datasheet for the definition of each bit in its mode register and extended mode register.

Note:

The definition of a mode register's bit field varies with different SDRAM density.

Caution when programming SDRAM's mode register

To effectively support STBus load 32 and store 32 packets, the LMI's SDRAM controller uses DT (SDRAM type) and BW (external data bus width) in the LMI_MIM register to determine the burst length.

Table 38: Determining burst length using the LMI_MIM register

Bus width (BW bit)	Burst length
00: 16-bit	8
01: 32-bit	8
10: 64-bit	4

For a 16-bit external data bus width, the LMI splits an STBus load 32 or store 32 packet into multiple SDRAM transactions, with a burst of 8 for each transaction. Therefore the BL field of the SDRAM device's mode register must be programmed to match the LMI's burst length behavior in the third column.

16 Flash and peripheral memory interface (FMI)

The FMI is a highly flexible memory device that is able to support a large range of memory components gluelessly. It accepts memory operations from the system and, depending on the address of the operation, either accesses its internal configuration space or one of the four possible external memory banks.

The position, size, clock frequency and memory type supported is dependent on how the associated control registers, FMI_BANK[0:3], are programmed.

Following reset, all banks start with the same configuration which allows the system to boot from a large range of nonvolatile memory devices.

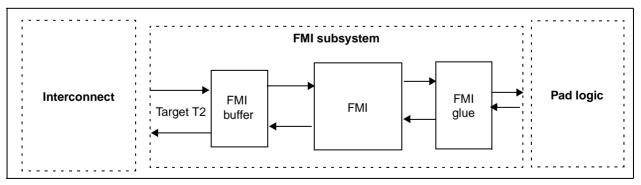

As part of the boot process, the FMI configuration registers should be programmed to match the memory supported in that system, defining the memory size, the location in the address and the device type connected. Each bank can only accommodate one type of device, but different device types can be placed in different banks to provide glueless support for mixed memory systems. Only 16-bit flash memory can be used to boot.

The STx5119 FMI features:

- FMI as bus master,
- support for four banks of 64 Mbytes, each of which may be independently configured,
- support for synchronous or asynchronous flash,
- asynchronous support for peripherals and SRAM,
- burst flash support (AMD AM29BL162C, STMicroelectronics M58LW064, Intel 28F160F3 compatible),
- SRAM support,
- 16-bit width data bus (boot is always from a 16-bit device),
- 2 Mbyte contiguous addressing, implemented as address subdecoding on bank 2 and 3,
- strobe/address phases generation,
- support for DVB-CI.

The FMI is allocated a 1-Gbyte region of the available memory map which is separated into two spaces. One is configuration space used to control the behavior of the FMI, the other a memory region which is mapped on to four configurable FMI banks. Boot bank is bank 0.

Figure 21: FMI subsystem main architecture

FMI endianness is fixed at system reset to little endian and cannot be changed dynamically. Bit positions are numbered left to right from the most significant to the least significant. Thus in a 32-bit word, the left-most bit, bit 31, is the most significant bit and the right-most bit, bit 0, is the least significant.

16.1 Supported burst flash memory devices

The FMI supports the following flash memory devices in banks 0, 2 and 3:

- AMD AM29BL162C,(bank 2 and 3)
- STMicroelectronics M58LW064A/B,
- Intel 28F800F3/ 28F160F3.

The FMI implements a superset of operational modes so that it is compatible with most of the main functions listed for the three flash families. See Table 39 for a comparison of the supported features.

	AMD	STMicroelectronics	Intel
Size	16 Mbits	64 Mbits	8/16 Mbits
Maximum ¹ operating frequency	40 MHz	10 MHz 60 MHz	
Data bus	16 bits fixed	16 bits	16 bits fixed
Main operations	Asynchronous single access write Sync burst read Asynchronous single access read	Asynchronous single access write Sync burst read Asynchronous single access read	Asynchronous single access write Sync burst read Asynchronous single access read

Ready for burst ⁸	No	Yes (R)	Yes (W)

Table 30: STMicroelectronics	, Intel flash features comparison
Table 59. ST Microelectronics,	, inter nash reatures comparison

1. The flash operating frequency, clock divide ratios and system frequency should be consistent with the maximum operating frequency.

- Modulo burst is equivalent to linear burst and sequential burst. Interleaved burst is equivalent to Intel burst. On AMD the burst is enabled by four asynchronous write operations. On STMicroelectronics and Intel devices the burst is enabled synchronously using the burst configuration register.
- 3. X latency is the time elapsed from the beginning of the accesses (address put on the bus) to the first valid data that is output during a burst. For STMicroelectronics, it is the time elapsed from the sample valid of starting address to the data being output from memory for Intel and AMD.
- 4. 10 to 12 only for F = 50 MHz
- 5. Y-latency is the time elapsed from the current valid data that is output to the next data valid in output during a burst.
- 6. See Section 16.4.5: AMD flash support on page 109.
- 7. When the pin is low, the device is busy with a program/erase operation. When high, the device is ready for any read, write operation.
- 8. These signals are used to introduce wait states. For example, in the continuous burst mode the memory may incur an output delay when the starting address is not aligned to a four word boundary. In this case a wait is asserted to cope with the delay.

16.2 Signal and strobe generation

The FMI generates strobe transitions on either edge of the reference clock. The relationship of the strobes is programmed inside the FMI, to allow strobe edges to be controlled with a resolution of half a clock cycle. This is most used for improving timing resolution (for example, extending hold time) for slow asynchronous peripherals (1/2 or 1/3 of the FMI subsystem clock).

At 108 MHz the extra resolution is not generally needed, and for synchronous interfaces, the FMI does not support negative edge transition.

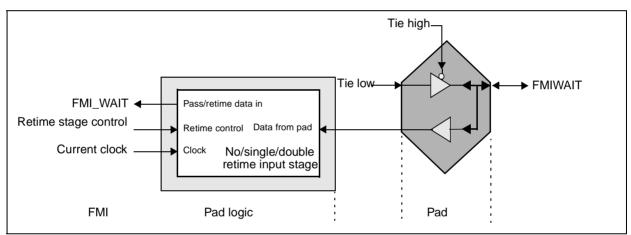

Note: For synchronous modes, the signals are synchronous to the rising edge of the current memory clock being used.

16.2.1 Input strobe generation

FMIWAIT

FMIWAIT may be passed to the generic FMI as a retimed input. The retimed input can be dynamically changed between a single retime input stage or a double retime input stage, selectable by the retime stage control input. Both retime stages are synchronized to the current clock. FMIWAIT uses the internal FMI control signal FMI_WAIT.

Figure 22: Synchronous input strobe pad logic connections

When accessing a device, the number of retime stages is programmable through FMI_GENCFG[3:2] as shown in Table 40.

Table 40: FMIWAIT retime stage control mapping

Number of retime stages	Retime stage control[1:0]	
0 (signal passed directly to the FMI)	1x	
1 (single retime stage)	01	
2 (double retime stage)	00 (default)	

The boot indicator (FMI_GENCFG[20]), an FMI register bit, is set by the software to logic 1 when the boot sequence is complete. Any subsequent reboot (hard or soft) forces this bit to be reset to logic 0.

16.2.2 Output strobe generation

External peripherals, such as memory devices and microprocessors, require control signals for their correct operation. These signals are generated internally by the FMI and are then passed to the pads. If necessary they are also inverted.

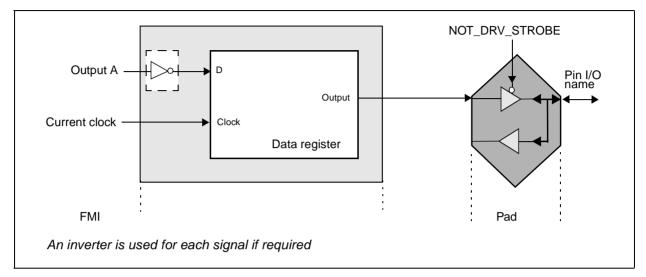

Table 41 details the signal connection for the internal FMI control signals to the external device pins.

Table 41: Control signal-to-pin connections

FMI signal name	Description	Pin I/O name
FMI_BE[0]	Byte enable 0	NOT_FMIBE0
FMI_BE[1]	Byte enable 1	NOT_FMIBE1
FMI_OE	Output enable	NOT_FMIOE
FMI_LBA	Flash device load burst address	NOT_FMILBA
FMI_RDNOTWR	Read not write	FMIRDNOTWR

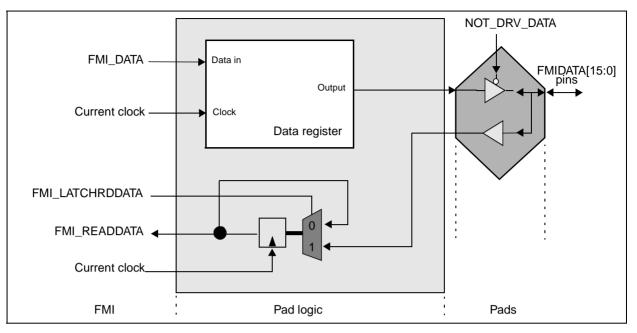

The FMI provides four chip selects for external devices dedicated to banks 0 to 3. These correspond to the pads as detailed in Table 42.

Table 42: Chip select signal-to-pin connections

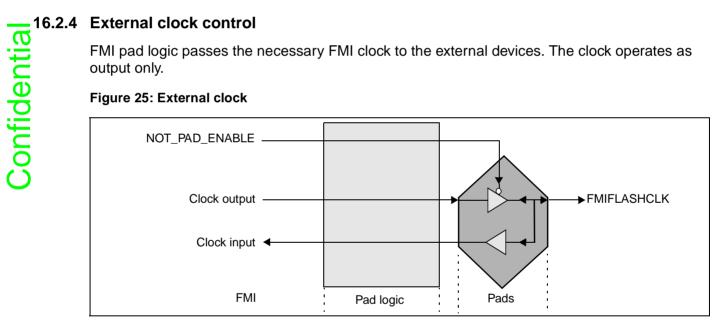

FMI signal name	Description	Pin I/O name
FMI_CSA	Chip select on bank 0	NOT_FMICSA
FMI_CSB	Chip select on bank 1	NOT_FMICSB
FMI_CSC	Chip select on bank 2	NOT_FMICSC
FMI_CSD	Chip select on bank 3	NOT_FMICSD

16.2.3 Data bus control

Figure 24: Data bus and output control

FMI pad logic passes the necessary FMI clock to the external devices. The clock operates as

16.3 Bank position and size

Region 3 of memory is organized into four banks of different size. Each bank is enabled and its size is set using the FMI bank sizing registers. The position and size of each bank is specified by programming the top address of each bank into the registers. This is done for address bits 29 to 22 giving a minimum bank size of 4 Mbytes.

Note: The boot memory is always located at the top of bank 0 as the C106 expects to boot from the bottom of region 0.

On the STx5119 the FMI can only boot from a 16-bit device.

0x7FFF FFFF 0x7FC0 0000	FMI BANK3 (FMI_CSD)

Table 43: ST20 FMI bank sizing register reset value

16.4 Bank options

The FMI can interface to a wide variety of SRAM, ROM, Flash, SFlash[™] and other peripheral devices. Each of the FMI banks can be set up separately to support different types of devices. There are restrictions on certain banks as can be seen in Table 44.

Table 44: Allowable bank options

	Bank 0	Bank 1	Bank 2	Bank 3
AMD flash	Ν	Ν	Y	Y
Intel/ST Flash	Y	N	Y	Y
Sub-bank decoding	N	N	Y	Y
DVB-CI	Ν	Y	Ν	Ν

A typical configuration is shown in Table 45.

Table 45:	Typical	FMI	configuration
-----------	---------	-----	---------------

FMI bank	Capability	FMI address	Size (Mbytes)
3	Asynchronous peripheral	0x7FC0 0000	8
2	Asynchronous peripheral	0x7F00 0000	8
1	DVB-CI	0x7F40 0000	496
0	Flash	0x4000 0000	512

The configuration is held in memory-mapped registers within the FMI. Three types of configuration registers are present: global, bank control (FMI_CONFIGn) and bank options (FMI_GENCFG and FMI_CONFIG_CTRLn).

Each FMI_BANK[n] (n = [0:3]) contains a set of four 32-bit registers that are used to control each bank depending on the type of device that is connected.

Table 46 describes how the configuration region of each bank is divided.

Table 46: FMI bank[n] control register formats

Register name	Description	
FMI_CONFIGDATA0	General parameters, see page 118	
FMI_CONFIGDATA1	Read parameters, see page 119	
FMI_CONFIGDATA2	Write parameters, see page 120	
FMI_CONFIGDATA3	General parameters, see page 121	
Reserved		

The type and organization of each set of bank registers is dependent on the value in DEVICETYPE (FMI_CONFIGDATA0) which defines the type of memory or device attached to that bank.

The interface can be configured either for an asynchronous nonmultiplexed address and data bus (SRAM/peripheral/flash interface) or for SFlash[™]. To configure an asynchronous nonmultiplexed device use FMI_CONFIGDATA0, FMI_CONFIGDATA1 and FMI_CONFIGDATA2. To configure for SFlash[™], set bit 26 (WE_USE_OE_CONFIG) in FMI_CONFIGDATA0 to and set FMI_CONFIGDATA3.

Both memory types and their associated control registers are described in Chapter 17: Flash and peripheral memory interface (FMI) registers on page 114.

16.4.1 Default configuration

Following reset, a default setting (in registers FMI_CONFIGDATA0 and FMI_CONFIGDATA1) is loaded into all four banks. This allows the FMI to access data from a slow asynchronous ROM memory.

Parameter	Bits	Default value				
FMI_CONFIGDATA0						
WAITPOLARITY	[25]	Active high				
LATCHPOINT	[24:20]	End of access cycle				
DATADRIVEDELAY	[19:15]	10 phases				
BUSRELEASETIME	[14:11]	4 cycles				
CSACTIVE	[10:9]	Active during read-only				
OEACTIVE	[8:7]	Active during read-only				
BEACTIVE	[6:5]	Inactive				
PORTSIZE	[4:3]	Value of the signal FMI_PRTSZ_INIT (8- or 16-bit)				
DEVICETYPE	[2:0]	Peripheral				
FMI_CONFIGDATA1						
ACCESSTIMEREAD	[30:24]	(18 + 2 = 20 cycles)				
CSE1TIMEREAD	[23:20]	0 phases				
CSE2TIMEREAD	[19:16]	0 phases				
OEE1TIMEREAD	[15:12]	0 phases				
OEE2TIMEREAD	[11:8]	0 phases				
CYCLENOTPHASE	[31]	Phase				
BEE1TIMEREAD	[7:4]	3 phases				
BEE2TIMEREAD	[3:0]	3 phases				

Table 47 gives the default state after an asynchronous boot. The remaining configuration parameters are not relevant for an asynchronous boot.

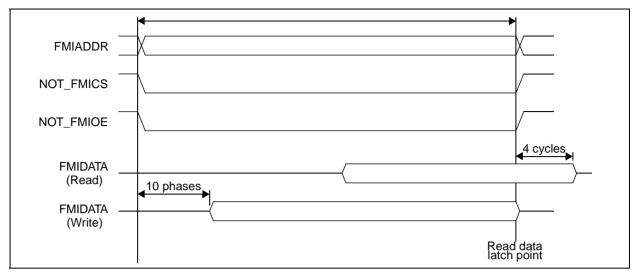

Figure 27: Default asynchronous configuration

As peripheral interfaces are used immediately after reset to boot the device the default state must be correct for either synchronous or normal ROM. An SFlash[™] device can be interfaced to normal ROM strobes with the addition of only the address valid signal and the clock. When the CPU has run the initial bootstrap, it can configure both the SFlash[™] device and the FMI to make use of the burst features.

Note: The flash devices are in asynchronous read mode after reset.

Caution: The process of changing from default configuration to synchronous mode is not interruptible. Therefore the CPU must not be reading from the device at the same time as changing the configuration as there is a small window where the FMI's configuration is inconsistent with the memory device's.

16.4.2 Clock reconfiguration for synchronous devices

Following reset, the clocks for synchronous interfaces are disabled. This is due to the default reset assuming a memory which may be accessed asynchronously.

To access the synchronous memory, set up the configuration state associated with that bank and program the required clock ratio associated with the memory type in the register FMI_FLASHCLKSEL.

The external clocks, and associated clock dividers, are then enabled by a write of 1 to the register FMI_CLOCKENABLE. Once enabled, any attempt to reprogram the clock ratios may have undefined effects.

16.4.3 Sub-bank decoding on bank 3

To support 2-Mbyte contiguous memory address space in the boot bank, bank 3 supports subdecoding. The bank 3 subdecoding is controlled by the logic block referred to as the CS control logic in Figure 28.

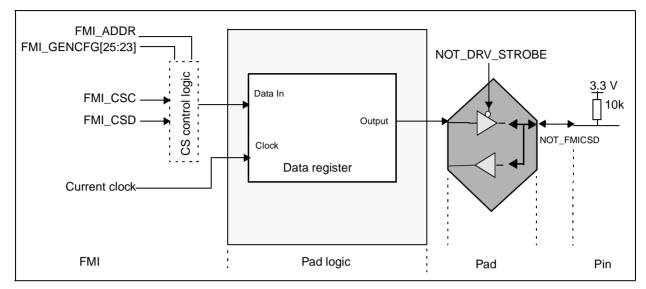

Table 48: Bank 3 sub-bank size control logic

Sub-bank size control (FMI_GENCFG[25:23])	Sub-bank size	Sub-bank selection control	
000	4 Mbit (512 Kbyte)	Unshifted address[19]	
001	8 Mbit (1 Mbyte)	Unshifted address[20]	
010	16 Mbit (2 Mbyte)	Unshifted address[21]	
011	32 Mbit (4 Mbyte)	Unshifted address[22]	
100	64 Mbit (8 Mbyte)	Unshifted address[23]	
101	1 Gbit (128 Mbyte)	Unshifted address[27]	
Others	1 Gbit (128 Mbyte)	Unshifted address[27]	

Table 49: Bank 3 control logic parameters

Bank 3 subdecoding control (FMI_GENCFG[22])	Sub-bank selection control	Outputs	Function	Inverter needed	Pin I/O name
0: Disabled	-	FMI_CSC	Bank 2 chip select	Yes	NOT_FMICSC
1: Enabled	0: Lower bank	FMI_CSD	Bank 3 lower	coded chip	
	1: Upper bank	Inactive	subdecoded chip select		
0: Disabled	-	FMI_CSD	Bank 3 chip select	Yes	NOT_FMICSD
1: Enabled	0: Lower bank	Inactive	Bank 3 upper		
	1: Upper bank	FMI_CSD	subdecoded chip select		

16.4.4 DVB-CI mode

Support for DVB-CI mode is documented in a separate application note.

16.4.5 AMD flash support

This allows AMD burst flash BAA signal support on banks 2 and 3 through MUXing with FMIADDR[25]. Bank 2 is set using FMI_GENCFG[27] and bank 3 using FMI_GENCFG[26].

16.5 Generic access cycle

Figure 29 shows a generic access cycle and the allowable values for each timing field are shown.

Figure 29: Generic access cycle

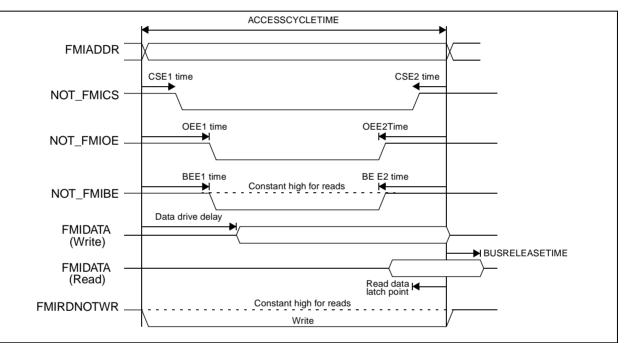

Table 50: Strobe timing parameters for peripherals

Name	Register	Bit	Programmable value
ACCESSTIME	FMI_CONFIGDATA1 FMI_CONFIGDATA2	[30:24] [30:24]	2 cycles + 0 to 125 cycles
BUSRELEASETIME	FMI_CONFIGDATA0	[14:11]	0 to 15 cycles
DATADRIVEDELAY	FMI_CONFIGDATA0	[19:15]	0 to 31 phases after start of access cycle
CSE1TIME	FMI_CONFIGDATA1 FMI_CONFIGDATA2	[23:20] [23:20]	Falling edge of CS. 0 to 15 phases or cycles after start of access cycle
CSE2TIME	FMI_CONFIGDATA1 FMI_CONFIGDATA2	[19:16] [19:16]	Rising edge of CS. 0 to 15 phases or cycles before end of access cycle
OEE1TIME	FMI_CONFIGDATA1 FMI_CONFIGDATA2	[15:12] [15:12]	Falling edge of OE. 0 to 15 phases or cycles after start of access cycle
OEE2TIME	FMI_CONFIGDATA1 FMI_CONFIGDATA2	[11:8] [11:8]	Rising edge of OE. 0 to 15 phases or cycles before end of access cycle.
BEE1TIME	FMI_CONFIGDATA1 FMI_CONFIGDATA2	[7:4] [7:4]	Falling edge of BE. 0 to 15 phases or cycles after start of access cycle

Name	Register	Bit	Programmable value
BEE2TIME	FMI_CONFIGDATA1 FMI_CONFIGDATA2	[3:0] [3:0]	Rising edge of BE. 0 to 15 phases or cycles before end of access cycle
LATCHPOINT	FMI_CONFIGDATA0	[24:20]	0: End of access cycle. 1 to 16: 1 to 16 cycles before end of access cycle.

Separate configuration parameters are available for reads and writes. In addition, each strobe can be configured to be active on read, write, neither or both.

Table	51:	Active	code	settings
-------	-----	--------	------	----------

CS/OE/BE active code	Strobe activity
00	Inactive
01	Active during read-only
10	Active during write-only
11	Active during read and write

16.6 FMI flash interface

16.6.1 Operating modes

Two different programmable read modes are supported:

- asynchronous single read,
- synchronous burst mode (default four words length: configurable to 1, 2, 4 and 8 words) using a specific lower frequency clock selected using the FMI_FLASHCLKSEL register.

Burst mode flash accesses consist of multiple read accesses which must be made in a sequential order. The FMI maps system memory operations on to one or more burst flash accesses depending on the burst size configuration, operation size and the starting address of the memory access.

Note: 1 Continuous burst is not supported by the FMI.

- 2 32-word burst size is partially supported by the FMI. The burst is interrupted when the required data has been read.
- 3 Asynchronous page mode read is not supported by the FMI.
- 4 Interleaved burst mode is not supported by FMI because of the implementation of multiple reads only using synchronous burst mode (feature provided by all the three families of flash chips adopted).

FMI supports a asynchronous single write.

The asynchronous single read/write uses the same protocol as that of the normal peripheral interface.

In Figure 30 a typical burst access with burst length of four words is shown.

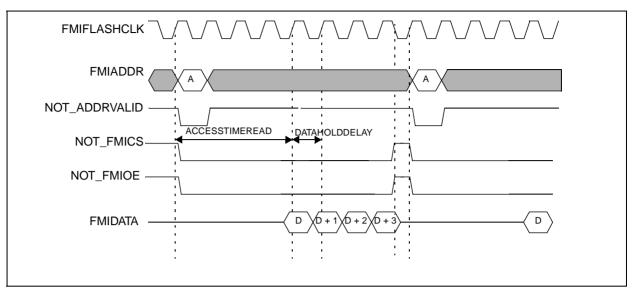

Figure 30: Synchronous burst mode flash read (burst length = 4)

The ACCESSTIMEREAD parameter is used to specify the time taken by the device to process the burst request. The rate at which subsequent accesses can be made is then specified by the DATAHOLDDELAY parameter, e1 and e2 delays can also be specified.

16.6.2 Burst interrupt and burst reiteration

The FMI interrupts the burst after the required amount of data has been read, thus making the chip select of the burst device inactive. This operation is allowed by all the three families of flash devices (burst read interrupt for an STMicroelectronics device, standby for Intel, terminate current burst read for AMD). Due to this operation, the flash device puts its outputs in tri-state. If a new burst operation is then required, a new chip select and load burst address is provided (FMI_LBA) to the memory chip.

If the flash interface is configured to a burst sequence of n bytes, and a burst read request of m bytes is presented to the FMI on the STBus interface, there are three possible outcomes.

• n = m

The FMI performs one burst access during which it gets the exact number of words as requested (see example A In Figure 31 with n = m = 8). Depending on the starting address, there is possibly a wrap that is automatically completed by the flash device. The wrap occurs when the starting address is not aligned on an *n*-byte word boundary. n > m If the starting address is aligned on an *m*-byte word boundary, the FMI gets *m* bytes from a single burst sequence as explained in the previous paragraph. Then the transfer on flash is interrupted making the chip select inactive. This terminates the burst transfer and puts the memory device in standby mode, waiting for a new request and starting address for a new burst.

If the starting address is not aligned on an *m*-byte word boundary, a first burst on the flash executes until the *m*-byte word boundary is crossed. The burst on the flash is interrupted and there follows another burst with a starting address that wraps to an *m*-byte boundary (directly given by STBus interface) to read the remaining data. After all the required bytes have been read, the burst access on flash can be interrupted.

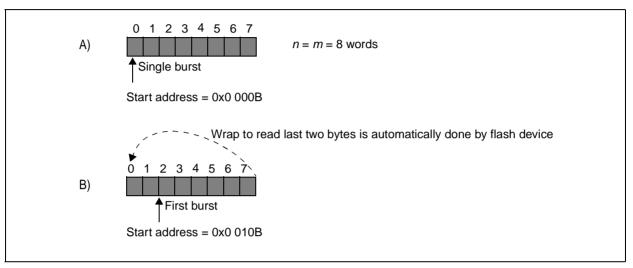

• *n* < *m*

The FMI needs to perform more burst accesses until it gets the required m words.

If the starting address is aligned on an *n*-byte word boundary, there are a series of flash burst accesses until the exact number of bytes is met.

If the starting address is not aligned on an *n*-byte word boundary, there is a first access on flash to read data until the *n*-byte word boundary is met. This access is then interrupted and new series of accesses are started on a new address provided by STBus (that eventually wraps at the *m*-bytes boundary). This is repeated until the exact number of bytes is reached. This happens in the middle of the last flash burst that is interrupted in the usual manner.

6.6.3 Synchronous burst enable

This operation is controlled by software and must only be performed when all other configuration registers in the FMI have been programmed.

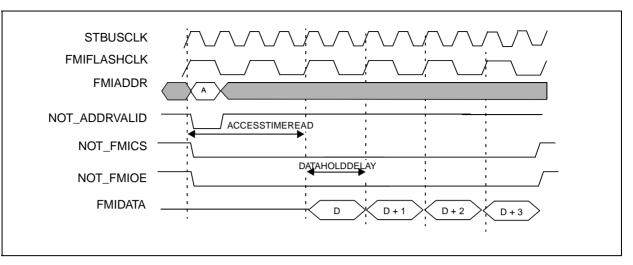

Table 39: *STMicroelectronics, AMD, Intel flash features comparison* on page 100, shows that for STMicroelectronics and Intel devices to operate in synchronous burst mode, the configuration parameters must be set in a special configuration register inside the memory device. The configuration software routine starts two asynchronous write operations for each bank of burst memory, where address and data, respect precise configuration rules. However, for AMD the burst enable is performed by a sequence of four normal asynchronous writes.

16.6.4 Lower clock rates

Many SFlash[™] devices operate in the 30 to 50 MHz clock range (Table 39: STMicroelectronics, AMD, Intel flash features comparison on page 100) whereas the FMI operates up to a clock frequency of 108 MHz. To deal with this difference, the FMI runs in a lower speed mode. The hardware in the FMI needed for this mode forces accesses to always start on the rising edge of the slower clock. It is up to the user to configure the other FMI timings, to set up and latch, on the appropriate edge of this slower clock.

Figure 32: Half speed FMI SFlash™ clock

16.6.5 Pull up resistors

Pins for FMI ADDR22 and FMI ADDR23 should be pulled up with an external resistor for correct operation of the device.

17 Flash and peripheral memory interface (FMI) registers

Addresses are provided as either the *FMIBaseAddress* or the *FMIBufferBaseAddress* + offset. The *FMIBaseAddress* is: 0x2020 0000. The *FMIBufferBaseAddress* is: 0x202F F800. All FMI buffer registers are nonvolatile.

FMI general parameters

2. The 64/128 byte burst mode is due to the possible usage of the AMD device that has a fixed 32-word burst length. STBus interface maximum transfer is 32 bytes on FMI, so in these cases the burst on flash is always interrupted.

register must be programmed in terms of flash clock cycles.

Note: Any bit in the configuration register, which is defined as reserved, should be set to 0. FMI_CONFIGDATA3 does not need to be configured for a normal asynchronous peripheral. The strobe on falling feature of FMI means only that strobes, data and address are generated on the falling edge of the SFlash[™] clock. This does not imply that the same signals are sampled on

the falling edge of the SFlash[™] clock. This does not imply that the same signals are sampled on the falling edge by the memories. The FMI assumes memory always samples on the rising edge anyway. The strobes on falling feature has been implemented only to possibly extend the hold time of half a cycle to help pad logic implementation.

18 System services

18.1 Brief overview

The system services block groups together a number of functions:

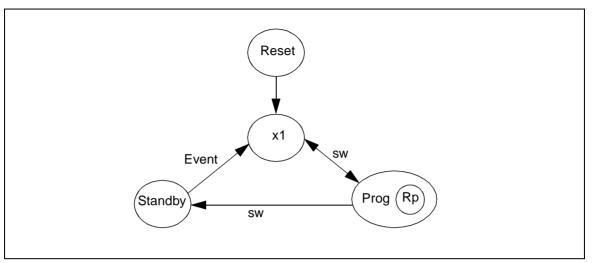

- clock generation and distribution,
- low speed reduced power monitoring and control,
- real-time counter,
- integrated clock recovery using a digitally-controlled oscillator (DCO),
- smartcard power control,
- reset control,
- CPU programmable interrupt.

Figure 33: STx5119 system services architecture

18.2 States of operation

Figure 34: States of operation diagram

There is one mode of operation which is clock master. Within this mode there are three states of operation:

- x1,
- programmable (reduced power mode exists within the programmable mode of operation),
- standby.

Following reset the system services block transitions into the x1 state causing all clocks to be sourced from 27 MHz. All others transitions into the x1 state after reset are through software by programming the MODE_CONTROL register or event-based from standby mode.

To program the divider channels the software must cause a transition to the x1 state, the subsystem clocks are shut down (zeroed) in a clean way and then re-started synchronously using the external 27 MHz clock. The divider channels can then be programmed. When programming is complete a further software transition is made into the programmable state, this transition causes a second clean switch to the newly programmed clock divider outputs.

It is possible to transition from programmable mode to standby mode with software. The return path transition to x1 mode only occurs if the low power alarm is activated. Also if there is an external interrupt (wake up) from the comms subsystem.

The reason standby transitions to x1 mode is because the PLL could be disabled within standby. Therefore no PLL clocks are running.

18.2.1 Programming the registers

After reset all registers are locked and cannot be written to. A write can only occur when the lock register is unlocked. The registers can be unlocked as in the procedure below.

- 1. Unlock the registers by writing the keyword followed by the bit wise inverse.
- 2. Configure the registers as required.
- 3. Lock the registers by writing a 1 to the KEY_LOCK bit (bit 8 of REGISTER_LOCK_CFG).

18.3 Clock generation and distribution

STx5119 clock generation provides the following features:

- multiple subsystem clocks allowing decoupling of the CPU from the interconnect for maximum performance,
- dynamic clock change for performance tuning or reduced power,
- FMI master-only clock generation and deskew,
- LMI master-only clock generation deskew is performed in the padlogic,
- digital VCXO clock recovery support for MPEG.

STMicroelectronics provides a basic initialization procedure for clock generation set up, which is available for standard modes.

For flexibility the clocking scheme is based on two PLLs and two quadruple synthesizers.

18.3.1 Subsystem clocks

The subsystem clocks are generated using the frequency synthesizer PLLs as shown in Table 53. The resulting ranges are used to divide the blocks among a number of clock domains.

Subovotom	Name	Clock free	Clock frequency (MHz)					
Subsystem	Name	Min	Max	Default	Source			
CPU	CPU_CLK	200	243	200	PLL1

Table 53: Subsystem clock frequencies

18.3.2 PLL clocks

The STx5119 uses two PLLs in a frequency synthesizer configuration, primarily driven from an external 27 MHz crystal.

The PLLs provide system clocks up to 620 MHz. These two clocks are individually selectable by the programmable dividers that source the clocks shown in Table 53, resulting in greater system flexibility.

PLL frequency calculation

The PLLs have three dividers which are referred to as M (pre-divider), N (feedback-divider) and P (post-divider). These dividers are located in the PLLx_CONFIGn registers. The output clock of the frequency of the PLL is controlled by binary values applied to the programmable registers as defined by the following formula:

18.3.2

Confidential

$$F_{(clockout)} = \frac{2 \times N}{M \times 2^{P}} \times F_{(refclock)}$$

where the values of M, N and P must satisfy the following constraints:

$$1 \le M \le 256, 1 \le N \le 256, 0 \le P \le 5$$

$$1 MHz \le \frac{F_{(refclock)}}{M} \le 200 MHz$$
$$200 MHz \le \left(\frac{2 \times N}{M}\right) \times F_{(refclock)} \le 650 MHz$$

$$1 MHz \le F_{(refclock)} \le 400 MHz$$

$$6.25 MHz \le \left(\frac{2 \times N}{M \times 2^{P}}\right) \times F_{(refclock)} \le 650 MHz$$

Table 54 gives subsystem frequencies for functional, reset and reduced power modes.

AUDIO_CLK	80		80		0	80

Table 54: Clock frequency requirement for different modes

1. During reduced power mode, the programmable dividers are sourced with 27 MHz and the functional divide ratio is applied. For this table the Func1 divide ratios are applied.

- 2. Reduced power cannot be used for semi-synchronous operation.
- 3. These frequencies are a fallback setting in case x1 to programmable mode is not functioning.

Note: The default reset values in the register PLLx_CONFIG0 will not result in the required PLL frequencies (399 MHz and 533 MHz). To achieve the correct frequencies, PLLA and PLLB must be programmed with the values 0x2404 and 0x4406 respectively following a reset. See Section 18.2.1: Programming the registers on page 124.

Programmable clock divider

To program the dividers with a particular divide ratio the following values should be used from Table 55.

Divider divide ratio	CLKDIVn_DEPTH ¹	CLKDIVn_SEQ[19:0] ²	CLKDIVn_HNO ¹	CLKDIVn_EVEN ¹

2. CLKDIVn_CONFIG0, CLKDIVn_CONFIG1

18.3.3 Frequency synthesizer clocks

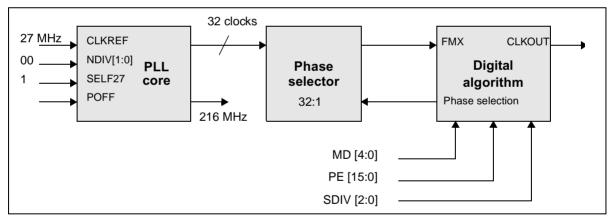

There are two quadruple frequency synthesizers used within the STx5119 with four programmable output clocks per frequency synthesizer. The clocks are generated by each frequency synthesizer using a fixed and stable 27 MHz reference clock. Internally a 216 MHz frequency is generated as well as thirty two 216 MHz clocks with 32 different phase offsets. Currently two outputs from frequency synthesizer B are spare.

The output clock is obtained by a digital algorithm which selects 1 out of 32 phases. Each output clock is configurable between 1 and 216 MHz.

Registers control the output frequency and set up using the following parameters:

- MD[4:0] in the [clock]_SETUP0 register: coarse selector for the phase taps selection (-1 to -16)
- PE[15:0] in the [clock]_SETUP1 register: fine selector for the phase taps selection (1 to 2**15)
- SDIV[2:0] in the [clock]_SETUP0 register: output divider (2 to 256) SDIV:
 - SDIV = 000 divides by 2,
 - SDIV = 001 divides by 4,
 - SDIV = 010 divides by 8,
 - SDIV = 011 divides by 16,
 - SDIV = 100 divides by 32,
 - SDIV = 101 divides by 64,
 - SDIV = 110 divides by 128,
 - SDIV = 111 divides by 256.

Figure 35: Frequency synthesis

The frequency of the output clock is given by the formula:

$$F_{out} = \frac{2^{15} \cdot F_{PLL}}{sdiv \times \left[\left(pe \cdot \left(1 + \frac{MD}{32} \right) \right) - \left((PE - 2^{15}) \cdot \left(1 + \frac{MD + 1}{32} \right) \right) \right]}$$

where $F_{PLL} = 216$ MHz.

To avoid glitches at the frequency synthesizer output, only the MD, PE and EN_PRG parameters can be changed.

Fs (kHz)	256 * Fs (MHz)	MD [4:0]	PE [15:0]	SDIV [2:0]
8	2.048	0x1A = 26	0x5100 = 20736	6

1. Audio decoder sampling frequency.

Table 57: S/PDIF frequency synthesizer (FS2) programming

S/PDIF_CLK (MHz)	MD [4:0]	PE [15:0]	SDIV [2:0]
12.288 (48 kHz x 256)	0x11 = 17	0x3600 =13824	4
11.2896 (44.1 kHz x 256)	0x13 = 19	0x6F05 = 28421	4
8.192 MHz (32 kHz x 256)	0x1A = 26	0x5100 = 20736	4

Multiplexing after the frequency synthesizer outputs allows clock switching when in standby mode (LP_MODE_SYNTH_DIS[n]). A glitch free multiplexer (GFM) switches cleanly between frequency synthesizer output when transitioning between the x1 and programmable states. See Section 18.5: *Standby mode* on page 130

For improved performance FS_CLK[6] can be used as an additional source clock for CLK_AUX. The switch between the divider clock output and FS_CLK[6] is glitch free and controlled by the ALT_TRANSPORT_SELECT register. The advantage of using a frequency synthesizer clock is the maximum frequency of 216 MHz with fine adjust capabilities.

18.4 Reduced power mode

Reduced power mode gives power saving on individual subsystems and is programmed through the REDUCED_POWER_CONTROL register. The reduced power is achieved by sourcing the divider channel with 27 MHz and using the existing programmed divide ratio to provide a divided 27 MHz subsystem clock output. Bit 9 of the register configures all dividers to reduced power mode. Bits [8:0] configures all dividers to reduced power mode for individual subsystems.

18.5 Standby mode

Low power control (standby mode) is the shut down of subsystems in aid of power consumption. The systems services block is kept operational with 27 MHz and restarts the subsystem clocks in the event of:

- low power alarm,
- external wake up.

For additional power saving the PLLs and frequency synthesizers can also be turned off.

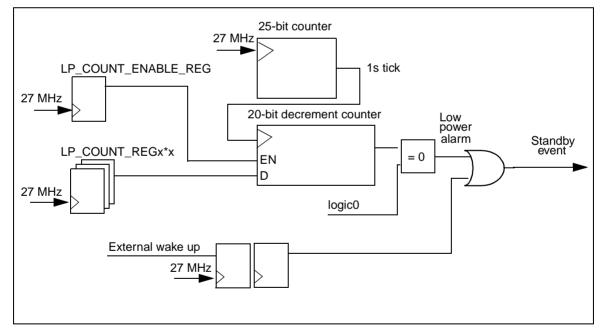

When transitioning back to x1, the subsystems are first clocked off 27 MHz. If registers need to be programmed this can also be done during the transition.

Standby mode, like reduced power mode, is software configurable. After programming the MODE_CONTROL register to the correct value the system services block transitions from F_{max} subsystem clock to logic 0. Software can also override standby mode so that instead of transitioning to logic 0 the resultant subsystem clock is 27 MHz.

18.5.1 Low power control

The low power alarm (LPA) is enabled by LP_COUNT_ENABLE. On assertion of LP_COUNT_ENABLE the LP_COUNT figure is decremented from the preloaded value on a 1 second timer tick. When the decremented count reaches 0 the low power alarm is asserted (the maximum count is 12 days before the low power alarm is asserted). This causes the control FSM to transition to x1 mode. The other event is the active high external wake up. As Figure 36 shows this is synchronized into the 27 MHz domain.

Figure 36: Low power control architecture

18.6 Real-time counter (RTC)

There are two real-time counters (RTCs) in system services, both run continuously within separate clock domains. RTC_LP runs from the 32 kHz LPCLKIN (LP clock domain) and RTC_27 runs from the 27 MHz CLK27IN (27 MHz clock domain). Both RTCs keep track of real time and run in parallel. System requirements determine which RTC is used. The 32 kHz LPCLKIN clock is generated inside the system services using the CLK_27 (27 MHz) input.

18.6.1 RTC_LP

RTC_LP is a 64-bit counter. It is shadowed by two 32-bit registers (RTCS_LSB_LP and RTCS_MSB_LP) in the 27 MHz domain. RTC_LP is never reset and is only programmed through the shadow registers.

Note: Data is always available for reading and the returned value always agrees with what was last written, even if not yet accepted by the RTC_LP.

When a previous write has not yet been accepted a second write cannot take place.

18.6.2 RTC_27

RTC_27 runs continuously from a divided CLK27IN tick. The control of the counter is identical to the control of RTC_LP. The counter tick is a divide of 27 MHz to make it as close to 32 kHz (32.768 kHz) as possible. The tick generated is 27 MHz / 824. Therefore the generated LPCLKIN is 32.767 kHz.

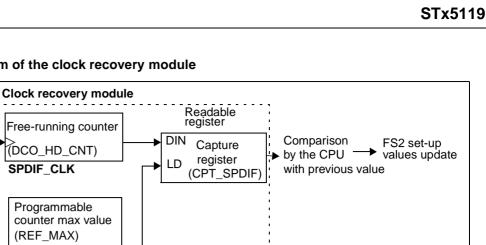

8.7 Integrated clock recovery (VCXO)

The integrated clock recovery system adjusts three local clocks generated from a triple frequency synthesizer which uses a fixed and stable 27 MHz clock produced by a crystal as a reference.

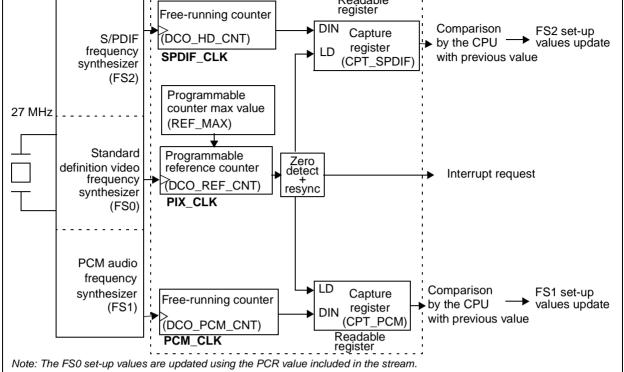

These three clocks are:

- PIX_CLK (27 MHz) used for standard definition display,
- SPDIF_CLK (74.25 or 148.5 MHz) used for S/PDIF output,
- PCM_CLK (256 * Fs where Fs can take several possible values, for example 32 kHz, 44.1 kHz, 48 kHz) used for audio output.

The VCXO (voltage-controlled crystal oscillator) clock recovery scheme is heavily reliant on interaction between hardware and software. It periodically adjusts the fine adjustment inputs on frequency synthesizer A and B for two of the outputs. The fine adjustment can be carried out independently, while the frequency synthesizers give improved jitter performance.

The recovery is done as usual for PIX CLK by comparing the 42-bit PCR value located in the adaptation field of the stream, with the local STC value when a packet arrived. This generates a potential correction that is applied to the PIX_CLK frequency synthesizer. The frequency synthesizer is programmed with new set-up values to slow or accelerate the clock.

For the audio PCM clock recovery two counters are used:

- a PCM free-running counter clocked by the PCM audio frequency synthesizer FS1.
- a reference counter clocked by the standard definition video frequency synthesizer FS0. The maximum value of this counter is programmable defining the time interval between two consecutive resets. This counter is used as a time-base.

When this reference counter resets, then the values of the free-running counter clocked at PCM_CLK is captured into a readable register. This event generates an interrupt to the CPU. The CPU reads the value and compares it with the previously captured value. The difference between two adjacent values gives an indication of the correction to apply to the PCM audio frequency synthesizer FS1.

The decision to correct the frequency synthesizer set-up is under the control of the software.

The same principle applies for the recovery of the SPDIF_CLK. A free-running counter is clocked with the S/PDIF frequency synthesizer FS2. The same reference counter is used. When this counter resets then the output of the free-running counter clocked at SPDIF_CLK is captured into a readable register.

The counters are 32-bit counters.

Á7/

18.7.1 Clock recovery commands

The clock recovery module accepts the following command:

Clock Recovery Reset: resets the reference counter, PCM counter and HD video counter. See also *DCO_CMD* on page 151.

18.7.2 Clock recovery interrupts

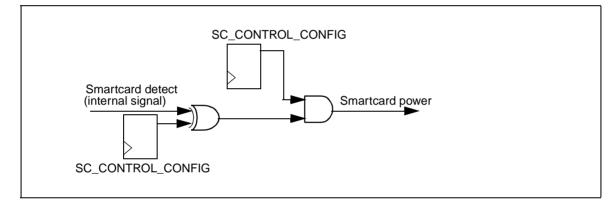

An interrupt line is available, generated from the internal clock recovery mechanism. The interrupt is asserted when the reference counter clocked at PIX_CLK resets.

This interrupt status is captured in the CMD register and only cleared when written.

18.8 Smartcard power control

Smartcard power control detects when the smartcard has been removed from the system. It is a hardware detect as power to the smartcard needs to be removed before software can respond. As can be seen from Figure 38 smartcard power can be disabled or inverted using SC_CONTROL_CONFIG[0].

Figure 38: Smartcard power control architecture

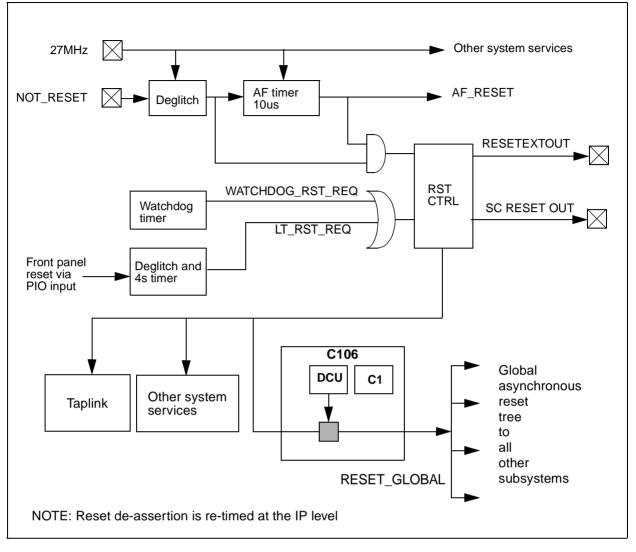

18.9 Reset control

Confidential

Figure 39 shows the number of different conditions that generate a subsystem or external reset. These are:

- NOT_RESET,
- watchdog reset,
- long time-out reset,
- smartcard insertion reset,
- programmable CPU interrupt.

Figure 39: Reset architecture

18.9.1 Combining resets

Confidential

When RESET_SELECT_ALT in the RESET_STATUS register is selected resets are combined into one pulse of a minimum 200 ms (stretched reset). The stretched reset is triggered internally by watchdog, long time-out, NOT_RESET and smartcard insertion signals as well as by an external reset. Internal resets are maskable. Therefore the smartcard insertion reset can be disabled using maskable bits.

18.9.2 Power on reset

The power on reset is either the 200 ms stretched reset or the normal reset. When the device powers up, if FMI address 23 is pulled high, the RESET_SELECT_ALT bit is written and the reset stretched.

18.9.3 Watchdog

The watchdog timer is enabled by the WD_COUNT_ENABLE in the WATCHDOG_COUNTER_CFG1 register. On assertion of WD_COUNT_ENABLE the WD_COUNT figure is decremented from the preloaded value on a 1 s timer tick. When the decremented count reaches 1 the watchdog reset is asserted. This causes a subsystem and global asynchronous reset.

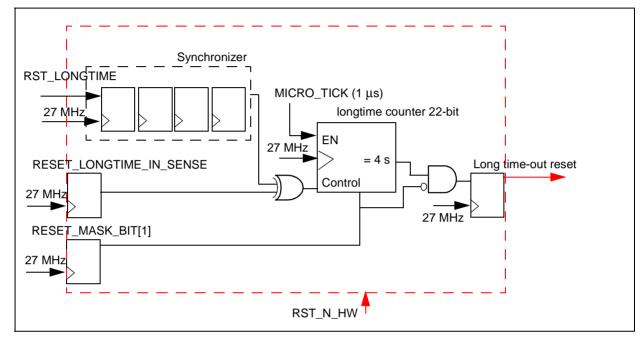

A masking bit in the RESET_STATUS register masks the watchdog reset.

18.9.4 Long time-out reset timer

The long time-out reset timer generates a reset signal if the RST_LONGTIME pin is active for approximately 4 s. The RST_LONGTIME pin is an enable of a counter that generates a 1 s timer tick. This timer tick clocks a second counter which generates a reset pulse when the count reaches 4 s, see Figure 40. A deglitcher provides a clean enable signal to the synchronous counter. The value of the count is zero when the enable is de-asserted.

A masking bit in the RESET_STATUS register masks the long time-out reset. See Figure 40.

Figure 40: Long time-out reset timer architecture

18.9.5 Smartcard reset detect

Confidentia

ل ۲۸

When the STx5119 detects that a smartcard has been inserted it asserts a reset pulse. A deglitcher removes any bounce in the signal from the smartcard. Smartcard reset is enabled by the SC_INS_RST_EN bit in the SC_INSERTION_RST_CFG register. The sense of the detect signal can also be inverted using the SC_DETECT_SENSE bit in the same register.

18.9.6 SDRAM interface

There are two resets to the SDRAM interface.

Asynchronous reset to the SDRAM

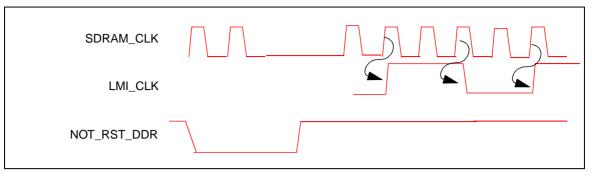

The SDRAM clock is disabled a number of cycles before and after the asynchronous reset.

Soft reset to the DLL

When system services is switched to x1 mode the DLL is reset so that the lower frequency of SDRAM and LMI clocks does not affect the DLL. When switching to programmable mode the DLL comes out of soft reset. Figure 41 shows the timing relationship between NOT_RST_SDRAM the SDRAM clock and the LMI clock.

Note: LMI_CLK is a divide by 4 of DDR_CLK.

Figure 41: SDRAM interface timing

18.10 CPU programmable interrupt

The CPU programmable interrupt is asserted when a count ranging from 1 to 100 ms reaches zero. The counter (CPU_INT_COUNT_CONFIG[6:0] in CPU_INT_CFG) is decremented on a microsecond tick. The reset condition is 10 ms but it can be programmed over a range of 1 to 100 ms. The generated interrupt is synchronized into the CPU clock domain. It's status is captured by a status bit in the CPU_INT_CFG register which is cleared when written to.

Note: Registers (except addresses 0x160 to 0x16F) are read only until they have been unlocked (write access). This is carried out with the REGISTER_LOCK_CFG register (address 0x300). See Section 18.2.1: Programming the registers on page 124.

19 System services registers

Addresses are provided as the SysServBaseAddress + offset.

The SysServBaseAddress is:

0x20F0 0000.

20 Programmable transport interface (PTI)

20.1 Overview

The PTI is a dedicated transport engine. It contains its own CPU and handles the transport deMUX functionality of the set-top box.

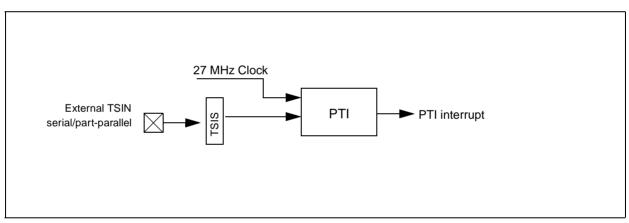

The transport stream sub system is a wrapper level that instantiates the TSIS, PTI and glue logic. The schemes that allow dual POD and DVBCI support are described in the Section 3.5: Transport stream processing on page 15.

The TSIN input can be configured as a serial or parallel input. The interface between the transport stream clock (TSBYTECLOCK) and the SYSCLK domain is confined to the TSIS block. The TSIS communicates with the PTI on system clock.

The PTI maintains an internal system time clock timer (STC) which keeps track of the encoder clock. The STC is clocked off the recovered 27 MHz clock which is derived from the clockgen integrated VCXO. The set-top box clock recovery software drives the VCXO in such a way that its output clock is locked onto the encoder's clock.

The ST20 sets up the PTI and loads its program through the T1 interface. On reception of a new transport packet the PTI writes its content to the ST20 memory space through the T2 interface.

Figure 42: PTI inputs and outputs

The PTI module parses and demultiplexes the transport stream, using a mixture of hardware and software running on an application specific processor called the transport controller (TC). The TC gives the PTI the level of flexibility normally associated with software based demultiplexing of transport streams without the overhead of this processing being placed on the ST20 CPU.

The PTI is configured by registers and programmed by two blocks of static shared memory contained within the PTI, one block containing instructions and the other data. The data block contains structures shared with the ST20 CPU plus structures private to the TC. Code for the TC is downloaded into the PTI instruction memory by a PTI software driver running on the ST20.

The functionality of the PTI is therefore defined by a combination of the PTI hardware, the software running on the TC, and the software driver running on the ST20. This arrangement allows great flexibility by changing the code to be run. Many parameters of the code are modified to change the behavior and features of the PTI. The TC code and PTI driver software are provided by STMicroelectronics. Different versions of these software components are available, with support for generic MPEG-2/DVB transport stream parsing, and demultiplexing.

Specific details of the data structures and mechanisms used to communicate between the TC and the PTI driver running on the ST20 are contained in the documentation for these software components.

PTI operation is controlled by a software API supplied by STMicroelectronics.

7939391A

The remainder of this chapter is a description of the hardware components of the PTI and the features and operation implemented by ST software.

20.2 PTI functions

The PTI provides great flexibility, since many features are implemented in either hardware, software or a combination of the two. What follows is a description of the features of the PTI when running the first version of the generic DVB code.

The PTI hardware performs the following functions:

- serial and parallel interface for transport stream input,
- support for incoming MPEG-2 transport streams with a data rate up to 138 Mbit/s,
- descrambling using the following algorithms:
 - DVB-CSA,
 - CBC, DVS042, OFB, CTS,
 - ECB, CBC, DVS042, OFB.
- framing of transport packets (sync byte detection),
- section filtering up to 32 x 8 bytes using three programmable filtering modes,
- CRC checking of sections (CRC32) and PES data (CRC16),
- DMA and buffering of streams in circular buffers in memory.

This behavior is changed with TC software:

- DMA of data stream to audio and video MPEG decoders via buffers in memory,
- fast search for packet ID (PID) using dedicated hardware engine,
- time stamp checking in two formats.

Software extends the hardware's capability:

- PID filtering of up to 96 PIDs,
- eight descrambling key pairs per PTI,
- adaptation field parsing PCR detection and time stamping,
- special purpose section filters allowing total flexibility in processing transport streams,
- demultiplexing of transport stream by PID, supported by hardware,
- communication to ST20 CPU of buffer state.

In addition to these transport device functions, the interface copies the entire transport stream or transport packets with selected PIDs from the transport stream through to the PTI output stream interface.

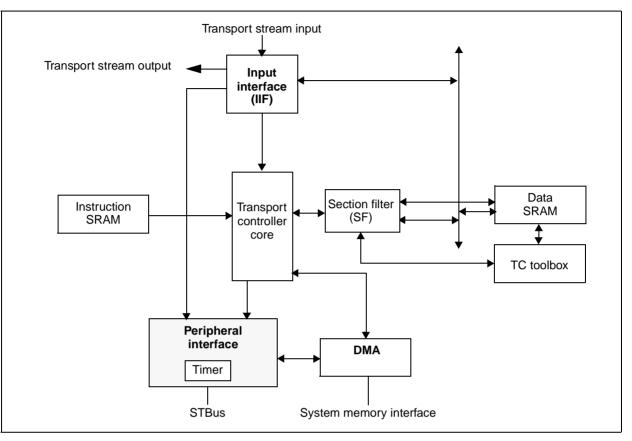

Details of how to control these features are contained in the PTI application programming interface (API) and the PTI software documentation for the particular version of the PTI code.

57

20.3 PTI architecture

The PTI consists of the TC containing the TC core, input interface (IIF), DMA, and peripheral interface blocks. This is illustrated in Figure 43.

20.3.1 Transport controller (TC)

The TC incorporates the TC core which implements the transport deMUX software. The TC core is a simple 16-bit RISC CPU which uses hardware accelerators to implement PID searching (SE) and section filtering (SF). There is also hardware support for CRC checking.

The TC is responsible for parsing transport packets delivered via the IIF, and controls the entire PTI operation via memory mapped registers. Processed transport data is passed out from the TC to the dedicated DMAs where it is written to ST20 memory via the STBus.

Search engine (SE)

The SE performs a table look-up on the PID to determine whether the current packet is required. It supports searching on up to 96 PIDs and also implements range-checking.

Section filter (SF)

The SF is a hardware accelerator block dedicated to the section filtering task. It supports a number of standard section filtering schemes (short matching mode, long matching mode, positive negative mode) and any software based filtering scheme. Standard filtering is implemented using a double RAM-based CAM.

The SF operates in two modes: automatic or manual.

Automatic mode

The SF takes over the entire filtering process, reading data directly from the TC core input register and writing directly to the output register. The TC merely reads the packet header, sets up the SF with the appropriate configuration, and sets it going. Breakpoints are allowed in the process to allow the TC to intervene and customize the filtering algorithm at specific points, allowing maximum flexibility at top performance (sometimes called semiautomatic mode).

Manual mode

The TC core is in overall control of the process but uses the dedicated SF to perform specific filtering tasks.

20.3.2 Shared memory

The PTI contains 5 Kbytes of data memory which is accessed as 32-bit words by the ST20 CPU and as 16-bit words by the TC. This memory is used to hold the private data structures of the TC and data shared between the two processors.

The 6-Kbyte instruction memory holds the instructions that the TC executes. It is accessed as 32-bits wide by both the TC and the ST20 CPU, and is loaded with code by the ST20 before enabling the TC. The ST20 cannot access the instruction memory while the TC is executing.

20.3.3 DMA

The DMA block is responsible for writing processed transport data to ST20 memory.

There is one DMA channel. DMA channel 0 is used for writing data to ST20 memory under the control of the TC, so that data is sorted into a number of circular buffers. Data can also be written directly to the video and audio decoders under the control of signals generated by the decoder FIFOs. A programmable delay (the holdoff time) is built into the data transfer to ensure all data has reached the decoder before the FIFO signal is read for the next transfer. Also, a programmable write length ensures that all data has storage room in the target upon arrival.

Channel 0 outputs single words or 4-, or 8-word bursts. It may also be configured to output data directly to the decoders.

The DMA block is controlled by a number of registers which are programmed by the TC software. Functions controlled by these registers include:

- setting up and manipulating the circular data buffers,
- configuring write channel (channel 0) operation,
- channel 0 status,
- memory map selection (programming mode).

20.3.4 Peripheral interface

The peripheral interface allows the PTI to interact with the ST20 and communicate data between them. It handles all address decoding (for example, DMA writes and interrupts) and allows joint access to the instruction and data SRAMs and configuration registers. It also implements the timer and time stamp functions and soft reset (see Section 20.4.2: Soft reset on page 161).

ل ۲۸

20.3.5 Timer module

The timer module in the PER contains the system time clock (STC) and three time stamp registers:

- packet start time register,
- audio PTS (presentation time stamp) latch register,
- video PTS latch register.

These registers are loaded with the STC value according to the events shown in Table 60.

Table 60: Timer module register update events

Event	Action
Rising edge of packet clock (packet start)	STC is loaded into the packet start time register
Beginning of audio frame output	STC is loaded into the audio PTS register
VSYNC	STC is loaded into the video PTS register

The packet start time register is read by the TC and used to determine the arrival time of a program clock reference (PCR). The CPU cannot directly access this register. TC software stores this arrival time together with the PCR in shared data SRAM so it can be read by the CPU.

The audio and video PTS registers are read directly by the CPU and used by driver software to synchronize the audio and video. Each register consists of two words to accommodate 33-bit time stamp values, one word holds the lower 32 bits and the other holds the most significant bit.

20.4 PTI operation

The programmable transport interface (PTI) performs the transport parsing and processing functions without intervention of the ST20 CPU. The block is controlled by the ST20 and communicates with it via a shared data SRAM block local to the PTI, registers in the PTI, data structures in the ST20 memory written by the PTI and an interrupt from the PTI.

The shared data SRAM is used to hold the main data structures for the PTI including:

- PID values,
- descrambler keys for each PID,
- control bits for each PID to set up DMA parameters, to mark the PCR PID, to control section CRC checking, and to mark PIDs which need copying to the selective transport output interface,
- PID state information, such as a transport or PES level descrambling flag, partial sections for filtering, partial section CRC values, and current continuity count values,
- descriptors and pointers to the circular buffers where the streams from each PID are sent,
- the last adaptation field and its time stamp from the local system clock.

Registers are provided to allow the ST20 CPU to initialize and control the block and to provide interrupt status and control.

20.4.1 Initialization

After device reset, the TC in the PTI is halted and the PTI block remains idle. It stays in this state until:

- the TC code is loaded into the instruction SRAM by the ST20,
- initialization is performed as described below,
- the TC is enabled by setting the TCENABLE bit of the TCMODE register high.

There are a number of initialization steps that must be performed before the TC is enabled.

- 1. The data SRAM must be initialized with any data structures required by the TC software.
- 2. The interrupt status registers must be cleared.
- 3. The IIFFIFOENABLE register bit must be set high to enable the input FIFO.

20.4.2 Soft reset

A soft reset feature is available on the PTI by setting a bit in the TC configuration register. The DMA should be flushed using register PTI_DMAFLUSH before the reset is initiated to ensure all outstanding signals on the bus are cleared.

20.4.3 Typical operation

When the TC is running, the software waits for a transport packet to arrive. Having detected the start of a packet, the TC code then sets up the PTI hardware search engine to perform PID filtering. The search engine searches a contiguous block of PID values within data SRAM for a match with the PID in the incoming transport packet header. If the packet is to be rejected, the software discards the packet and waits for the next packet to arrive. If the packet is one to be processed, the TC examines the data structure for the PID in the data SRAM to determine what other processing is required. The type of transport packet is recorded in this data structure by the ST20. The PTI driver sets variables in this data structure to configure the TC software to perform various tasks.

Typical tasks might be:

- descrambling at the transport or the PES level with a key pair,
- section filtering, with a set of filters and section CRC checking for streams containing sections,
- directing the output stream either to a circular buffer in memory or to a compressed data FIFO of an audio or video decoder,
- enabling or disabling a stream,
- appending or indexing extra information for further data processing by the ST20.

Having examined the PID data structures, the TC sets up the rest of the hardware in the PTI to perform the required descrambling and DMA operations before starting to parse the rest of the packet. Processing varies depending on the contents of the transport packet, which includes:

- PES data,
- section data,
- adaptation fields,
- continuity count fields,
- time stamp.

Typical processing for different packet types and fields is described in the rest of this section.

PES data

Transport packets which contain PES data and are not rejected by PID filtering, CRC checked and descrambled if required. The PES data is DMA transferred either into a circular buffer or to a decoder compressed data FIFO. The DMA features of the PTI buffer a PES stream in memory and then transfer the data to a decoder without the CPU being involved. Optionally an interrupt is generated to the ST20 when the buffer for a PES stream has data added to it and the state of the buffer changes from empty to nonempty. An interrupt is raised and an error flag set in the data SRAM if the buffer overflows. In such cases, the most recent data is lost.

Section data

Transport packets which contain section data and are not rejected by PID filtering, are subjected to section filtering on each section or partial section in the packet.

The PTI contains a hardware section filter which implements two standard filter modes:

- short match mode (SMM): 32 filters of 8 bytes each,
- long match mode (LMM): 16 filters of 16 bytes each.

Positive/negative matching mode is also supported.

Section filtering is highly flexible. Any subset of the filters, including all or none, are applied to any PID, and filtering modes are mixed within an application.

When a section passes the filtering, the complete section is written to the ST20 memory space, either to a circular buffer or to defined locations for a set of sections.

The PTI hardware also automatically detects (using the section syntax indicator bit) if CRC has been applied to the section, and performs CRC checking if required. If the CRC check fails, the TC software removes the incorrect section from the section buffer, discards the current PID, and waits until a new packet arrives (detected by the unit start indicator). CRC checking is enabled or disabled, and the TC can also be programmed to keep a corrupt section.

The TC software uses a bit in the interrupt status registers to raise an interrupt for the ST20 signalling a buffer having a section placed in it.

There are no restrictions on any of:

- the alignment of the sections in transport packets,
- the lengths of sections other than those in the MPEG-2 standard,
- the numbers of sections in a packet when filtering standard sections.

Section filtering is implemented by a mixture of TC code with the hardware section filter. Alternatively, it may be performed purely in TC code to implement a small number of longer or special purpose filters. In this case there may be some restrictions on the minimum length of a section or the number per transport packet, to ensure that the processing is performed within the period of one transport packet interval.

Adaptation fields

Typically only the program counter reference (PCR) would be extracted from this field although the TC software could extract other data.

If a PID is flagged as the source for PCR values then any adaptation field in a transport packet with this PID containing a PCR has the PCR value extracted and stored in the data SRAM. The value is stored with a time stamp, which is the time when the transport packet arrived, as given by the system time clock (STC) counter value. An interrupt is raised to the ST20 and the interrupt bit itself is used as a handshake for the processing of the PCR by the ST20. Until the bit is cleared, no more PCRs are captured.

The STC counter is clocked by the 27 MHz input clock to the device and is initialized by the ST20 CPU.

Continuity count field

The TC software uses this field to check for missing transport packets. If a continuity count error is detected, the software discards any partial units of data, such as a partially complete section, and search for a new data unit starting point.

20.4.4 Direct output of transport data

Concurrently with the parsing, processing, and DMA transfer of the transport packets, some or all of the transport stream can be copied to an external interface, for example, an external IEEE 1394 controller. The ST20 software directs specific packets to be output, with or without

descrambling. Modifications of the transport stream, including modification of tables and substitution of packets, are possible by suitable programming of the TC.

20.5 Interrupt handling

The PTI may interrupt the ST20 under a number of conditions, for example when a DMA operation changes a buffer from being empty to nonempty, or in the case of an error condition. The interrupt is generated by the TC writing into one of the 64 interrupt status register bits. These bits are ORed together to produce one interrupt and fed to the interrupt controller via the interrupt level controller. The ST20 CPU then uses this interrupt to schedule a process to deal with this condition.

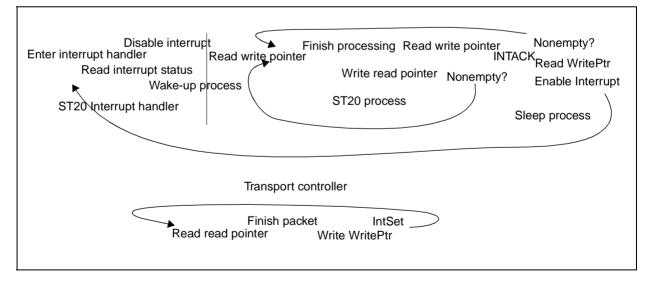

The TC sets a given interrupt by writing to the appropriate bit position in the interrupt status register and the ST20 resets interrupts by writing to the appropriate bit position in the appropriate interrupt acknowledge register. The ST20 determines which interrupts are currently set by reading the appropriate interrupt status register.

The ST20 enables or disables interrupts by writing 1 or 0 into the appropriate bit position in the appropriate interrupt enable register. Using this mechanism, the ST20 processes a buffer until a read to the write pointer (held in the data SRAM) shows the buffer to be empty. The process then clears the status bit which corresponds to that buffer by writing 1 to the corresponding interrupt acknowledge register bit.

The detection of the empty condition on a buffer and the acknowledgement of an interrupt does not lock out the TC from writing the write pointer after the ST20 has checked, and setting the interrupt status bit before the ST20 has acknowledged. The buffer state must be reconfirmed before waiting on a semaphore for that buffer. Rechecking the write pointer avoids data being left in the buffer until the next data arrives and the TC sets the interrupt again. If the buffer is still empty then the ST20 process enables the interrupt by setting the correct interrupt enable bit before making the process wait on a semaphore.

Figure 44 shows the TC and the ST20 processes and mechanism described above.

Figure 44: PTI buffer interrupt handling

Note: At any given time each process is at any point during the critical regions of code. There is no implied timing for each step of a process only an ordering of steps.

After the buffer has been refilled the TC sets the interrupt status bit causing the PTI interrupt handler to be run. When the interrupt handler finds the buffer process semaphore status bit is set then the interrupt handler signals to the semaphore to restart the process and disable that

interrupt bit. Therefore, the process itself disables the interrupt at the PTI level, and only enables it when it is about to sleep. An error condition would be handled in a similar manner.

The association of interrupt bits with particular conditions and events is determined by the TC code and the corresponding PTI driver running on the ST20 CPU.

20.6 DMA operation

The PTI contains a DMA controller which is programmed by the TC and the ST20 CPU. The channel 0 is used to write or read data to or from circular buffers defined by a base and a top pointer. There is also a read and a write byte pointer.

The TC uses DMA channel 0, a write only DMA, to send the data from a transport packet to a circular buffer in the ST20 memory space, or when required, directly to a decoder mapped on to a fixed memory location. Since the TC reloads the registers of channel 0 at the start of processing each transport packet, this allows payloads from transport packets with different PIDs to be output to different buffers. Channel 0 is configured to write data directly to the decoders by specifying the address to be written to in the appropriate buffer registers. When using this feature channel 0 should be set to holdoff mode.

It is also possible to configure channel 0 to ignore the decoder ready signal. This feature should be used with caution as it allows data to be written without flow control.

During operation the read and write pointers are examined by the hardware to determine if there is data in the buffers to be transferred. If there is data in the buffer and the request line for that channel is active then the data is transferred and the read pointer updated. If channel 0 DMA is writing into the buffer then the write pointer is updated by the TC; otherwise the ST20 CPU updates the write pointer after adding data to a buffer.

Once each transport packet has been output on channel 0, the DMA write pointer of the corresponding buffer data structure in the PTI data SRAM is updated. If the transport packet did not contain the end of a complete data unit such as a section, a temporary write pointer variable is used. This is done so that the ST20 process only sees a complete unit of data to be processed. The temporary write pointer is available for reading by the TC software in a special register. When the data unit is complete, the write pointer used by the ST20 process is updated and an interrupt is set to signal to the ST20 process that data is in that buffer.

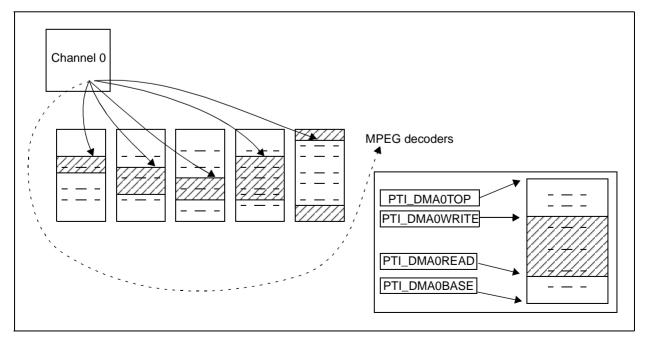

Figure 45: DMA channel

20.6.1 Circular buffers

The inset in Figure 45 shows how the buffer pointer registers are used to implement circular buffers for the DMA channel. The base register points to the base word of the buffer, and must be 16-byte aligned, so bits 0 to 3 must be zero. The top register points to the top byte of the buffer. If a circular buffer is being used then this address must be one byte below a 16-byte aligned address, so bits 0 to 3 must be 1. The buffer for channel 0 is reduced to a single address by setting the top register equal to the base register. In this case, the data is written to a fixed address defined by the write pointer and the write pointer is not updated.

The read and write buffers point to the next word to be read or written respectively.

At initialization the read and write pointers are set to the same value, so that the buffers are empty. The base and top pointers are initialized to point to the beginning and end of the buffers.

20.6.2 Flushing the DMA

Before doing a PTI soft reset (see Section 20.4.2: *Soft reset* on page 161), the DMA must be flushed to ensure it restarts cleanly without any outstanding request, grants or valid signals. This is performed using register PTI_DMAFLUSH.

20.7 Section filter

The section filter in the PTI hardware and TC software parses the section information in an MPEG-2 transport stream packet. Sections that pass the filter are transferred via the channel 0 DMA to ST20 memory. These sections have a fixed format and are defined by the MPEG-2 systems specification¹.

The data sections arrive at a faster rate than the system processes them, so a filter selects only those sections that are required and thus reduces the required processing rate. In addition, the sections that are used to construct tables are repeated regularly, so it is possible to build up an information table by capturing a proportion of them using one set of values in the filters, and then capturing the remainder of the table by setting the filters up to select the missing sections.

The hardware filter system looks for a match to the programmed filters, for example, using short match mode the match would be to a total of 32 filters of 8 bytes each. Each bit of each of the filters may be individually masked, so that no comparison is performed on that bit of the filter. In addition to the filtering operation the PTI performs CRC checking on the sections which match a filter. The CRC result is programmed to be acted upon for:

- all sections,
- no sections,
- only those sections that have the section syntax indicator bit set via bits in the PID data structure read by the TC code.

A 1-byte result report is output when sections are accepted.

A filter mask word in each PID data structure specifies which set of filters is applied to sections in a transport packet with that PID.

Filter matching is programmed by writing a set of masks and filters in the CAM memory. The CAM has two memory cores named CAMA and CAMB.

Each even 4-byte word memory address of the CAMA or CAMB memory array is a set of filter bytes, and each odd word address is either a set of filter bytes or mask bytes. A configuration bit is used to enable the masks. With masks enabled the total number of filters and masks available

^{1.} Generic Coding Of Moving Pictures And Associated Audio: Systems, Recommendation H.222.0, ISO/IEC 13818-1

is 16 x 16-byte or 32 x 8-byte filter plus mask sets. If masks are not required each CAM has 32×16 -byte or 64 x 8-byte filters.

The filters and masks are arranged in columns, interleaving one layer of filter data and, if masks are enabled, its relevant mask. The first entry to CAMA is a 32-bit word formed by the first byte of each of the first four filters. The first entry to CAMB is a 32-bit word formed by the first byte of each of the fifth to eighth filters. The second entry to the CAMA, when masks are enabled, will be a 32-bit word formed by the first byte of each of the masks of the first four filters and so on.

The position of the first filter in the memory is also programmable. Figure 46 illustrates different examples of CAM configuration.

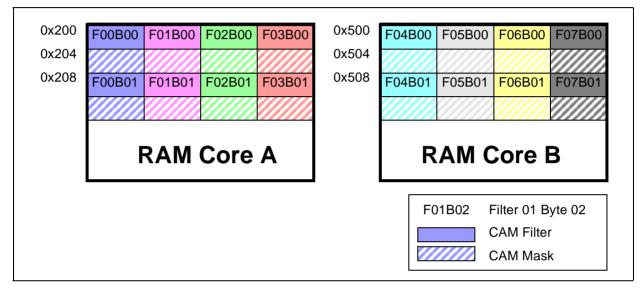

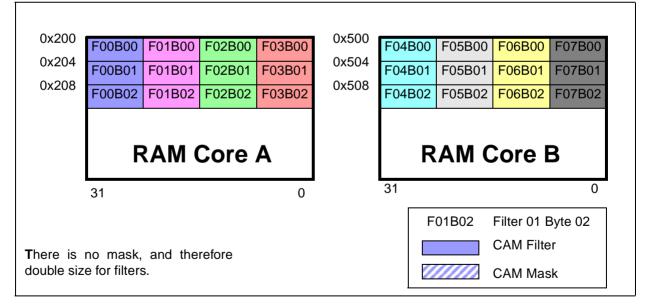

Figure 47: Memory organization with CAM_CONFIG NOT_MASK bit = 0 (masks enabled)

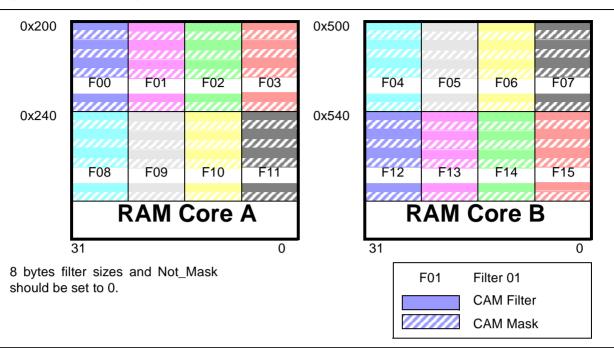

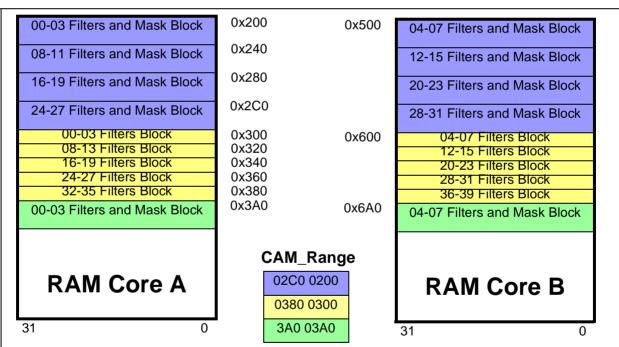

Figure 48: Memory organization for 16 filters

This example has filters for three different types of streams. The second (40 filters in yellow) are without mask. It has been assumed (see the memory address) that the filters for all cases are 8 bytes filters. To select between the different types, the CAM_Range register should be as shown over these lines. It shows the expected programed values for each of the sets in different contexts.

20.7.1 Automatic and manual modes

The SF operates in automatic or manual mode.

Automatic mode

In automatic mode the entire filtering process is performed in the SF with no intervention by the ST20. The ST20 processes the packet header, sets up the SF with the required configuration. and starts the SF engine. The SF then reads data directly from the TC input register and parses the entire payload, outputting section data to the TC output register.

To allow the TC to intervene and customize automatic filtering, breakpoints are set at the following events:

- after filtering any section (wanted or unwanted),
- after a wanted section has been output.

This enables the TC to add extra filtering, recover unwanted sections, or intervene between sections.

Breakpoints are enabled by setting the appropriate bits in the SF configuration register.

Manual mode

In manual mode the TC core controls the filtering process, writing section data in order to the SF header registers and reading the results from the SF, effectively using the section filtering and CRC modules as special purpose hardware engines.

Standard filtering modes supported are:

- short match mode (SMM): matches on CAM A or CAM B,
- long match mode (LMM): matches on CAM A filter n and CAM B filter n,
- positive/negative matching mode: matches on CAM A filter n and not CAM B filter n.

20.7.2 Filtering modes Standard filtering m • short match m • long match m • positive/negativ Standard filtering is outputs of which ar five bits of data and Standard filtering is performed by means of two CAM 32-bit wide memory cores (A and B), the outputs of which are ANDed to give the final result. CAM A has an additional register containing five bits of data and one bit to enable not matching. CAM lines are enabled or disabled using mask registers. Almost any CAM-based filtering match over 18 bytes can be programmed. The mapping of data to CAM A and CAM B for a single filter on each of these modes is shown in Table 61 to Table 63.

20.7.3 CRC checking

A CRC check is performed after the section has been processed by the section filter. If the check fails the software ignores the corrupt section in the circular buffer and waits for it to be transmitted again. The address of the start of the section is stored in a temporary register, and when the packet is encountered again in the data stream this address is loaded and the section data is directed to the correct circular buffer, where it overwrites the corrupted data.

20.7.4 Section filter registers

The section filter is configured and controlled by the TC software via a set of registers. These perform the following functions:

- section filter set up and configuration: automatic/manual mode; filter mode; CRC type; mask enable; breakpoint enable,
- section filter run,
- section filter header data,
- section filter process data: section filter state, CRC state, DMA write address,
- CAM engine configuration: number of filters in memory, filter length, first filter in memory, prefetch ability,
- CAM matching results,
- CAM mask data,
- CAM not matching results,
- selection of memory map (programming mode).

21 Programmable transport interface (PTI) registers

Addresses are provided as the *PTIBaseAddress* + offset.

The PTIBaseAddress is:

0x20E0 0000.

21.1 DMA registers

PTI_DMA0STATUS	
----------------	--

DMA channel 0 status

7	6	5	4	3	2	1	0
		Reserved			DMAFIFOFULL	DMADOVERFLOW	DMA0DONE

Address: *PTIBaseAddress* + 0x1018

Type: Read/write

0

Reset:

Description: The PTI_DMA0STATUS register shows whether DMA channel 0 overflowed. This is only used when debugging TC code. The TC code is normally designed to read the DMA0OVERFLOW bit and signal this condition to the ST20 software via one of the interrupt status bits. The interrupt bit is also used as a handshake that the ST20 software has acknowledged the condition. Data is discarded by DMA channel 0 if the buffer it is writing overflows.

[7:3] Reserved

[2] DMAFIFOFULL

If set to 1, the input fifo has reached a full condition and stalled the interface to the TC, preventing any data loss. Writing 1 clears the flag.

[1] DMA0OVERFLOW

If 1, the channel 0 circular buffer overflowed. Reset by writing 1 to this bit.

[0] **DMA0DONE**

Set to 1 after inserting the last byte of the stream. This tells the DMA to flush data from the FIFO into memory.

Reset to 0 by the DMA on completion. This occurs even if no data has been put in the FIFO.

PTI_DMA0BASE

DMA buffer base address

31 30 29 28 27 26 25 24 23 22 21 20 19 18 17 16 15 14 13 12 11 10 9 8 7 6 5 4 3 2 1 0

DMA0BASE

Address: *PTIBaseAddress* + 0x1000

Type: Write only

Description: Holds the base address of the DMA buffer for the DMA channel. This address must be aligned to a 16-byte boundary, so bits 3 to 0 must be written as 0. Bits 31 to 30 of this address must be the same as bits 31 to 30 of the corresponding PTI_DMAnTOP address register. The DMA channel 0 register would be set up for each PID in the PID data structure in the PTI data memory.

PTI_DMA0HOLDOFF DMA hold off time

assuming CD_REQ[n] is valid.

PTI_DMA0READ

DMA buffer read address

31 30 29 28 27 26 25 24 23 22 21 20 19 18 17 16 15 14 13 12 11 10 9 8 7 6 5 4 3 2 1 0

DMA0READ

Address:	PTIBaseAddress +	- 0x100C
Augu 633.	I IIDaschuuless i	071000

Type: Read/Write

Reset: Undefined

Description: The register holds the read address within the DMA buffer for the DMA channel. The address in the register is always a pointer to the next byte of data to be read except when the buffer is empty. The pointer must remain between the addresses defined by the base and top register. The channel 0 register would be initialized for each PID in the PID data structure in the PTI data shared memory, and an updated read pointer is written into the same data structure. The read pointer is initialized to be equal to the write pointer. As data is read from the buffer, the hardware updates the read pointer. The ST20 software must perform the following checks:

If the read address is not less than the top address, then the read address must be wrapped round to the base address.

If the read address is equal to the write address then the buffer is empty and data should not be read.

[2:1] DMA0CDSELECT

 Selects which NOT_CDREQ is checked when working in CD FIFO mode.

 00: NOT_CDREQ is not checked
 01: NOT_CDREQ[1] signal is checked

 10: NOT_CDREQ[2] signal is checked
 11: NOT_CDREQ[3] signal is checked

When 00 is selected channel 0 works under CD_REQ and holdoff mode, but it is assumed that the CDREQ signal is always high when holdoff time is reached.

[0] DMA0WORNOTBURSTMODE[0]

See DMA0WORNOTBURSTMODE[1]

PTI_DMA0TOP

DMA buffer top address

31 30 29 28 27 26 25 24 23 22 21 20 19 18 17 16 15 14 13 12 11 10 9 8 7 6 5 4 3 2 1 0

0x1010 0x1004	DMA0TOP
Address:	PTIBaseAddress + 0x1004
Туре:	Write only
Description:	This register holds the top address of the DMA buffer for the corresponding DMA channel. If the buffer size is not zero then this address must be one less than a 16-byte boundary, so bits 3 to 0 must be written as 1. Bits 31 to 30 of this address must be the same as bits 31 to 30 of the corresponding DMAnBASE address register. For channel 0 only, if the buffer size is zero then this address must be equal to the corresponding DMAnBASE address. The DMA channel 0 register would be set up for each PID in the PID data structure in the PTI data SRAM.

PTI DMAOWRITE

DMA buffer write address

31 30 29 28 27 26 25 24 23 22 21 20 19 18 17 16 15 14 13 12 11 10 9 8 7 6 5 4 3 2 1 0 0x1020 **DMA0WRITE** 0x1008 Address: PTIBaseAddress + 0x1008 Type: Read/write Reset: 0x00 Description: This register holds the write address within the DMA buffer for the DMA channel. The address in the register is always a pointer to the next location for a byte to be written. The pointer must remain between the addresses defined by the base and top registers. The DMA channel 0 register is set for each PID in the PID data structure in the PTI data SRAM and an updated write pointer is read from the same data structure. The write pointer is initialized to be equal to the same address as the read pointer. As data is written into the buffer, the write pointer is updated, and, after reaching the top pointer address, wraps around to write the next byte at the base pointer address. In the case of channel 0 the DMA hardware updates the write pointer, the TC copies this back to the data SRAM at the end of a packet, and the CPU should read the pointer from the SRAM.

Type: Read only

Reset: Undefined

Description: An interrupt is set when any bit of one of these registers is 1. The PTIINTSTATUS[3:0] registers are used by the TC to raise an interrupt to the ST20 by writing 1 to a bit in one of the registers. Each of the four registers has 16 bits. All 64 bits are ORed together to produce a single interrupt for the PTI.

Once the TC has set the INTSTATUS bits to 1, each bit stays set until the interrupt is acknowledged by the ST20 software by writing 1 to the corresponding bit of the corresponding PTIINTACK register. An interrupt is masked by writing 0 to the corresponding enable bit of the corresponding PTIINTENABLE register.

22 MPEG video decoder

22.1 Overview

The STx5119 MPEG video decoder is a real-time MPEG1 and MPEG2 decoder. It is compliant with the main profile and main level specified in ISO/IEC 11172_2 and ISO/IEC 13818-2.

As a picture (frame or field) decoder the MPEG video decoder needs CPU support for each picture.

When a decoding task is launched by the CPU, the MPEG video decoder starts to read the video elementary stream stored in an external memory through the interconnect. The area in memory where the stream is stored is called the bit buffer. The decoded picture is reconstructed (written in external memory) in macroblocks (MBs). In this document, reconstruction may be also called "main reconstruction". Each area in memory where a decoded picture is stored is called a frame buffer.

An interrupt informs the CPU when decode is completed or when a problem occurs. The decoder stops automatically when:

- all macroblocks have been decoded and it has found a start code different from a slice start code or
- when it has reached a programmed read limit.

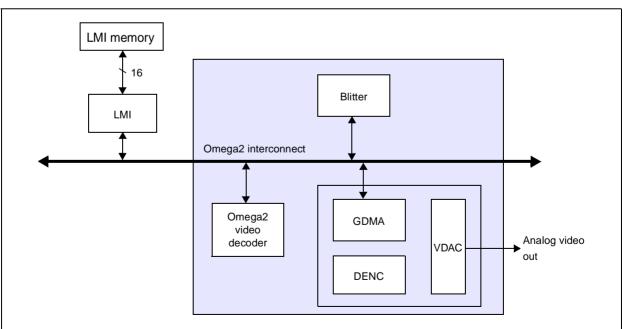

The MPEG video decoder supports two extra features which are not part of the MPEG standard:

- possible simplified B decoding, see Section 22.5.6: Simplified B decoding on page 202,
- error statistics, see Section 22.5.5: Error statistics on page 201.

Main functions

Figure 50 shows the video decoder in the STx5119 environment.

Figure 50: MPEG video decoder in the STx5119

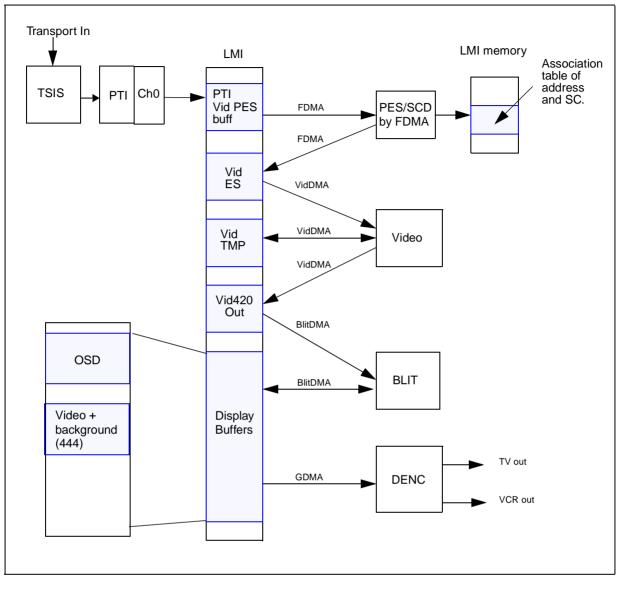

7939391A

Figure 51 shows the video decode data flow.

The PTI channel 0 circular video buffer is accessed by the FDMA which is a linear linked list machine. The synchronization is described in the following paragraph.

The host CPU is interrupted by a programmed timer event from system services, for example every 10 ms. The interrupt routine reads the ch0 write pointer from the PTI; using this, and the previous write pointer, a single pass linear access is activated using a dedicated process (PPSCD) running on the FDMA (with hardware assist) to perform PES parsing and start code detect.

The FDMA PPSCD process generates an elementary stream (ES) buffer in main memory and an association table which can be placed in external memory or local SRAM.

Each entry of the PPSCD table contains the following information:

- start code value,
- PTS if present,
- start code offset in PES buffer,
- start code address in the ES buffer.

This table is accessed by the video driver running on the host CPU. The ES video buffer is accessed directly using the linear DMA engine inside the video decoder. This block generates

several intermediate buffers during the prediction and reconstruction phases of decode before generating a final 420-Mbyte video buffer.

The video buffer is read directly by the blitter which performs multiple passes to format convert and blend the video buffer with a background and OSD overlay before rendering a final 4:2:2 display buffer.

The picture composed by the blitter is always frame based. The final presentation buffer is read by the GDMA which drives the digital encoder to produce component and composite video output. The GDMA should be programmed to access the presentation buffer field based.

22.3 Buffer organization

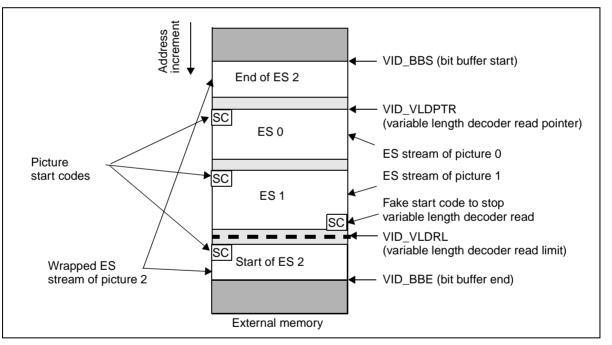

There are two types of buffer in the MPEG decoder:

- Bit buffer: area in external memory where the bitstream is stored,
- Frame buffer: area in external memory in which decoded pictures are stored.

22.3.1 Bit buffer organization

The FDMA writes the ES of each picture in external memory. Each picture ES may be stored linearly anywhere in the memory.

Figure 52: Bit buffer organization

The use of VID_BBS and VID_BBE is optional. It allows a memory area to be defined in which ES can be wrapped (see Figure 52).

When a decode is launched, the variable length decoder reads data until it reaches a start code different from a slice start code. It can be the picture start code of the subsequent picture, or a fake start code added at the end of the picture to stop the variable length decoder. The variable length decoder read process can also be stopped with VID_VLDRL (see *Stream pointers for variable length decoder read access on page 197*).

22.3.2 Frame buffer organization

The video decoder stores both frame and field pictures in a buffer which corresponds to a frame buffer. However a frame is reconstructed (whether as one frame picture or two field pictures), the final buffer has the same frame organization. When a frame picture is reconstructed, the whole buffer is filled. When a field picture is reconstructed, half the buffer is filled. The other half is filled after the second field is reconstructed.

Figure 53 is an example of a frame buffer with an odd width and height (3 macroblocks x 3 macroblocks).

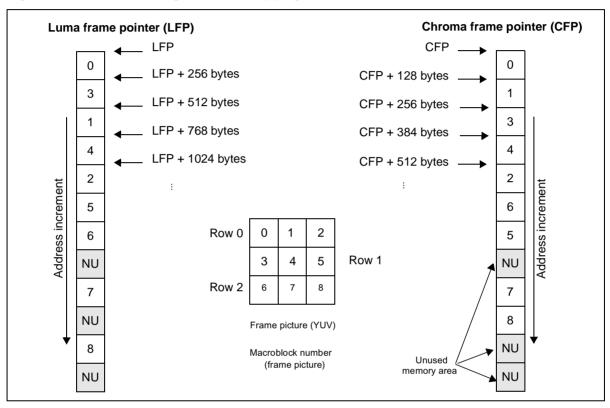

Figure 53: Frame buffer organization, mapping of 3 x 3 macroblocks

Memory is wasted with an odd number of vertical or horizontal macroblocks and this has to be taken into account when allocating memory space for frame buffers.

The formulas below give the size of frames buffers depending on macroblock width and height:

- LumaBufferSize = MBwidth * ((MBheight+1) DIV 2)*2 * 256
- ChromaBufferSize = ((MBwidth+1) DIV 2)*2 * ((MBheight+1) DIV 2)*2 * 128

Where DIV correspond to the integer part of a division:

x DIV y = integer part of (x/y)

A luminance macroblock contains16 words of 128 bits. Inside this macroblock, data is grouped by field and stored in the order, left part of top field, right part of top field, left part of bottom field, right part of bottom field. A description is given in Figure 54.

Chroma macroblock (Cb + Cr) data contains 8 words of 128 bits. The chroma macroblocks are stored in the same order as luma data (left part of top field, right part of top field, left part of bottom field) but a word of 128 bits contains 8 bytes of Cr data and 8 bytes of Cb data. A description is given in Figure 55.

Figure 54: Y macroblock storage

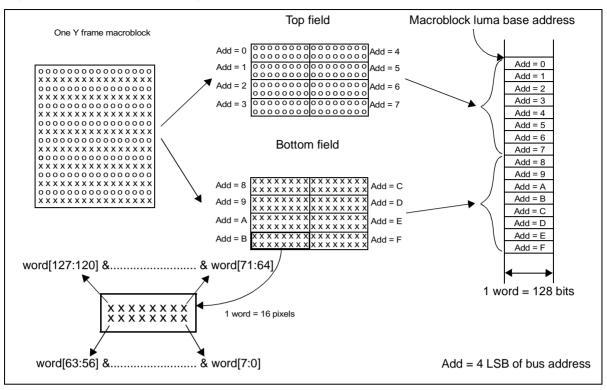

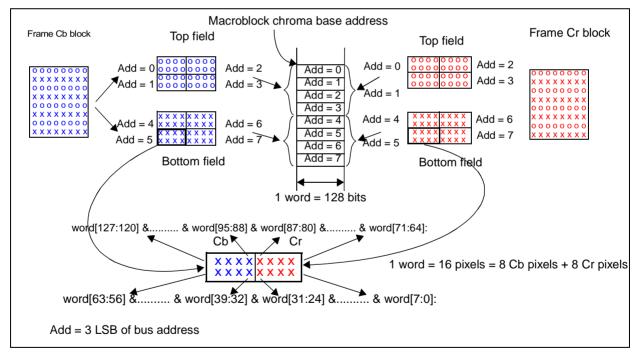

Figure 55: Cr/Cb macroblock storage

Address calculation in frame buffer

Macroblock position to address formula

MBnb	=	MB number (from 0 to <i>frame_size</i> - 1)
MBrow	=	MB row (from 0 to frame_height - 1)
	=	MBnb DIV frame_width
MB col	=	MB column (from 0 to frame_width - 1)
	=	MBnb MOD frame_width

Luma base address of the macroblock (MBrow, MBcol)

YMBba = Luma macroblock base address = ((MBrow DIV 2) x *frame_width* + MBcol) x 512 + (MBrow MOD 2) x 256

Chroma base address of the macroblock (MBrow, MBcol)

CMBba = Chroma macroblock base address = (((MBrow DIV 2) x frame_width + MBcol) DIV 2) x 512 + (MBrow MOD 2) x 256 + (((MBrow DIV 2) x frame_width + MBcol) MOD 2) x 128

Address to macroblock position formula

For Luma:

MBrow = ((addres	s DIV 512) DIV frame	_width) * 2 + ((address DI	/ 256) MOD 2)
------------------	----------------------	----------------------------	---------------

MBcol = (address DIV 512) MOD frame_width

For chroma

```
If ((frame_width MOD 2) = 1) AND (((address DIV 512) MOD frame_width) = (frame_width DIV 2))
```

then

MB_row= (((address DIV 512) * 2) DIV frame_width) * 2 + ((address DIV 256) MOD 2) + ((address DIV 128) MOD 2) * 2

else

```
MB_row= (((address DIV 512) * 2) DIV frame_width) * 2 + 
((address DIV 256) MOD 2)
```

end if

MBcol = (((address DIV 512) * 2) + ((address DIV 128) MOD 2)) MOD frame_width

22.3.3 Memory requirement

Video decoding requires a large amount of external memory for frame buffers and bit buffers. The exact need depends on the application.

Frame buffers

The maximum size of a frame buffer, for PAL pictures (720 x 576 pixels), is 5.014 Mbits (3.318 Mbits for luma frame buffer and 1.696 Mbits for chroma frame buffer, see Section 22.3.2 for details).

A minimum of three frame buffers is required to decode field pictures. A minimum of four is needed for frame pictures.

For trick modes (slow, normal or fast, backward or forward play), the number of frame buffers is much higher, depends on the speed of the decoder and the required fluidity quality.

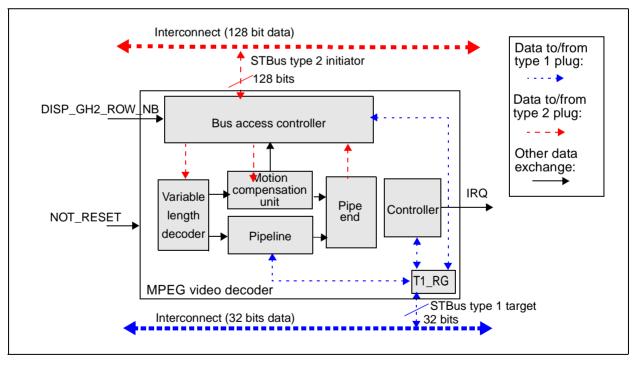

Bit buffer

The memory need in term of bit buffer is application dependant. The constraint imposed by the standard (ISO 13818-2 annex C), called video buffering verifier (VBV) can be applied on the ES or on the PES buffer. If it is applied on the PES buffer, the application must take into account the PES headers' size.

22.4 Video decoding tasks

A task is the decoding of a single picture. It is specified by the task instruction set up before the decoding of each picture in register VIDn_TIS.

Figure 56: MPEG video decoder block diagram

22.4.1 Controller

STx5119

The control of decoding tasks is managed by the controller block. The controller block:

- holds some debug registers: VID_DBG2, VID_VLDS, VID_VMBN, VID_MBE0, VID_MBE1, VID_MBE2 and VID_MBE3,
- holds the VID_EXE register to execute a decoding task and manages its synchronization on both clock domains,
- holds the VID_SRS register to do a soft reset,
- provides a set of interrupts which gives the status of the decoding process.

22.4.2 Variable length decoder

The variable length decoder is the first stage of the decoding pipeline. The bitstream is read from the bit buffer into the variable length decoder FIFO.

The variable length decoder performs the following functions:

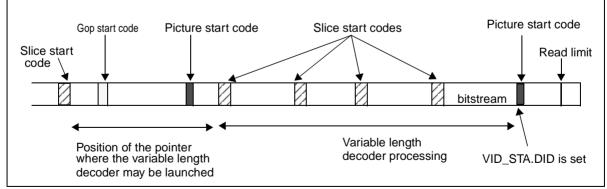

- variable length decodes the slice layer, macroblock layer and block layer,
- decodes the macroblock address increment and process skipped macroblock,
- decodes the motion vectors and delivers them to the motion compensation unit,
- detects bitstream errors and conceals corrupted and missing data (see Section 22.5.4: *Error recovery* on page 198),
- provides the number and the location of corrupted macroblocks in the picture (see Section 22.5.5: *Error statistics* on page 201).

The variable length decoder is launched by the VID_EXE register for each picture to be decoded. When the variable length decoder is launched with a pointer defined in byte units, processing starts at the exact byte location, but the data sent to the variable length decoder in its FIFO is aligned on a 128 bytes burst, that is the eight LSB of the pointer are ignored for memory access.

The variable length decoder may be launched with a pointer not aligned with a picture start code. The internal state machine of the variable length decoder, when a decoding task is launched, is to search only for slice start codes. When the first slice start code is detected, processing starts (Figure 57).

During the decoding task the variable length decoder FIFO requests data when there is space for one burst, that is when the FIFO is up to half full.

The variable length decoder enters in an idle state at the end of the decoding process when it detects a start code different from a slice start code. If there is no start code at the end of the picture in memory, the start code may be inserted by the application software at the very end of the picture. If no start code has been found, then the variable length decoder automatically stops on the read limit pointer (VID_VLDRL). Analyzing the bitstream after the end of a picture (when no start code is present) is not recommended because the variable length decoder may find other slice start codes and generate an overflow error (DOE interrupt).

22.4.3 MPEG pipeline

The variable length decoder sends run length coefficients to the MPEG pipeline. The pipeline processes the six blocks of every macroblock in the following order: Y0, Y1, Y2, Y3, Cb and Cr (refer to Macroblock structure in MPEG 2 standard, ISO 13818-2). The pipeline performs run length decoding, inverse zig-zag, inverse quantization and the inverse DCT. It holds a set of two quantization tables (intra and nonintra).

22.4.4 Motion compensation unit

In parallel, the motion compensation unit computes the predictors. Predictors are fetched from the appropriate reference frame buffer and processed according to the macroblock type and the motion vectors sent by the variable length decoder. When the macroblock is an intra macroblock, no predictor is fetched. For nonintra macroblocks, four bursts of data are always read per direction (forward or backward), two for luminance data and two for chrominance data. A luma burst is always 15 words of 128 bits and all words belong to the same field. A chroma burst is always nine words of 128 bits and all words belong to the same field. The motion compensation unit does not compute the predictor addresses in the reference picture. This task is performed by the bus access controller.

22.4.5 Pipe end

Finally, macroblocks are reconstructed by the pipe end, by adding coefficients from the pipe and the predictors from the motion compensation unit. Then macroblocks are sent to the reconstructed frame buffer through the bus access controller and the interconnect.

22.4.6 Bus access controller

The bus access controller performs read and write accesses to the frame buffers and read accesses to the bit buffers. It receives requests from the blocks, computes the addresses corresponding to the requests, arbitrates the requests and finally performs the memory access on the STBus. For prediction accesses, the bus access controller receives motion vectors and the macroblock type from motion compensation unit.

The STBus interface is used to read the bit buffer for the variable length decoder, for the prediction and the reconstruction processes. The packet size is programmable through the register CFG_VIDIC. The CPU is interrupted with bit ROPC in VID_STA if R_OPC flags an error during a transaction.

22.4.7 Register accesses

The T1RG interface is an STBus target and implements a 32-bit data interface for registers. Registers are also implemented on 32-bit width data. This interface uses little endian mode.

If a nonsupported opcode or a nonexistent address is presented to this interface, then a response packet is generated containing one response cell for each request cell received. The R_OPC is asserted to flag the error and the R_DATA returned by the interface is "dummy". The CPU is interrupted with bit R_OPC (VID_STA). The MPEG video decoder does not check inconsistent operations between the opcode and the byte enable. It is the byte enable which is taken into account prior to the opcode.

Plug	Load	Store
T1_RG	LD4	ST4

Table 66: Supported opcode for T1_RG

22.5 Video decoding

22.5.1 Control of decoding

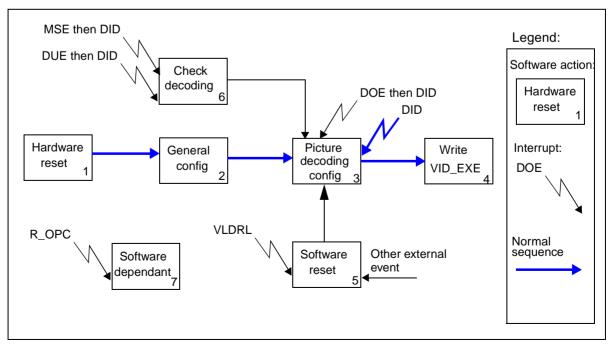

The control is performed by the CPU. The CPU launches the decoder one picture at a time.

Decoding performed without error

The normal sequence is described below.

- 1. Hardware reset,
- 2. General configuration of the MPEG video decoder (see General configuration on page 196),
- 3. Picture decoding configuration (see Picture decoding configuration on page 196),
- 4. Launch decoding by writing in VID_EXE LSBYTE.
- Loop to action 3 on a DID (decoder idle) interrupt. See description of VID_STA in Chapter 23: MPEG video decoder registers on page 203 for more details on interrupts).

Figure 58: Software and hardware interactions

7939391A STMicroelectronics Confidential 195/543

Abnormal cases

This covers decoding tasks that end by an interrupt different from DID or that is interrupted by a software reset. See below all the different cases and the possible software action.

• DOE interrupt

For overflow errors the decoder can be programmed for the next decoding task, no reset or specific action is needed. The software may decide whether to display the decoded picture.

• DUE interrupt

For underflow errors the decoder can be programmed for the next decoding task, no reset or specific action is needed. The software may read debug registers (6) to decide to display or not the decoded picture.

• MSE interrupt

For syntax or semantic errors the decoder can be programmed for the next decoding task, no reset or specific action is needed. The software may read the error statistic registers (VID_MBEx) registers (6) to decide whether to display the decoded picture.

• VLDRL interrupt

The decoder has reached the read limit without having completed the decoding task and is in an unknown state. A soft reset (5) must be performed before executing the next decoding task.

• R_OPC interrupt

Software decides what to do (7).

• Other external event

Software can decide to interrupt the decoding task at any time for several reasons: for example a channel switch or the decoding task is too long (overtime or overrun). The current decoding task can be interrupted at any time by a software reset (5).

It is not recommended to write in VID_EXE during a decoding task, that is, when VID_STA.DID = 0, because the current and the next decoding tasks may fail. To execute a decoding task correctly while another one is still active, STMicroelectronics recommends stopping the current one by writing to VID_SRS.

22.5.2 General configuration

Confidential

Vote:

The general configuration consists of CFG_VIDIC (video decoder interconnect configuration) and VID_ITM (interrupt mask).

22.5.3 Picture decoding configuration

Quantization table loading

The two quantization matrices (intra and nonintra) used by the inverse quantizer must be initialized. Since there are no built-in quantization matrices, they must be loaded either with default matrices or with those extracted from the bitstream by the CPU.

Quantization tables do not need to be loaded at every decoding task. If they are only present in the bitstream at the beginning of a sequence, they may be loaded only for the first picture.

The quantization tables are written in registers VID_QMWIP and VID_QMWNIP.

Decoded picture size

VID_DFW gives the picture width in number of macroblocks and VID_DFH gives the number of rows of macroblocks in the frame picture. The whole number of macroblocks in the frame picture is held in VID_DFS.

This data is extracted from the sequence header and is relative to the frame picture format.

Picture pointers for decoding

Before the decoding of each picture, the following frame buffer pointers must be set up:

- VID_RFP, VID_RCHP: reconstructed frame pointers for luminance and chrominance for main reconstruction,
- VID_FFP, VID_FCHP: forward prediction frame pointers for luminance and chrominance,
- VID_BFP, VID_BCHP: backward prediction frame pointers for luminance and chrominance.

VID_FFP, VID_FCHP, VID_BFP and VID_BCHP define the areas in memory for the predictors. How these four pointers are used depends on the prediction mode. The rules are given below. Pictures are always stored as frames, and to access a field (top or bottom), the starting address of the frame must be defined.

- P-frame picture (frame, field or dual-prime prediction) VID_FFP and VID_FCHP are set to the address of the predictor frame. VID_BFP and VID_BCHP are not used.
- B-frame picture (frame or field prediction) VID_FFP and VID_FCHP are set to the address of the forward predictor frame. VID_BFP and VID_BCHP are set to the address of the backward predictor frame.
- P-field picture (field, 16 x 8 or dual-prime prediction) When decoding either field, VID_FFP and VID_FCHP are set to the address of the previous decoded I or P frame. VID_BFP and VID_BCHP are not used.

• B-field-picture (field or 16 x 8 prediction)

VID_FFP and VID_FCHP are set to the address of the frame in which the two forward predictor fields lie. VID_BFP and VID_BCHP are set to the address of the frame in which the two backward predictor fields lie.

For I-picture decoding, no predictors are necessary, but VID_FFP and VID_FCHP must be set to the address of the last decoded I or P-picture for use by the automatic error concealment function.

For the P-field picture, an on-chip mechanism selects the pointers which must be used for the prediction between the forward frame and the reconstructed frame pointers. If the decoded field is the first field, the prediction is done in the forward reference frame. If it is the second field, the prediction is done using both forward and reconstructed frame pointers. The field number (first or second) is computed by the MPEG video decoder. It may be overwritten by the application with FFN (in VID_PPR). This may be useful for trick mode applications.

Picture parameters

These parameters are extracted from the bitstream. They have to be programmed in VID_PPR.

Decoding task instruction

Decoding task instructions are programmed in VID_TIS. This register gives options for error recovery and decoding (simplified B decoding).

Stream pointers for variable length decoder read access

The starting position of the encoded picture in the external memory must be programmed in the variable length decoder read pointer register (VID_VLDPTR).

A variable length decoder read limit may be set in the register VID_VLDRL. When the read pointer reaches VID_VLDRL (variable length decoder read limit), reading in the buffer is stopped and the VLDRL is set in VID_STA.

A bit buffer area can be defined with VID_BBS (bit buffer start) and VID_BBE (bit buffer end).

- If these registers are left in their reset state (0x0000 0000) or if the same value is written in both of them, they have no effect.
- If different values are programmed in both registers when the internal variable length decoder read pointer reaches VID_BBE it jumps to VID_BBS. This allows a video ES to be wrapped in a predefined memory area.
- Note: The variable length decoder read pointer (VID_VLDPTR) has to be programmed before each decoding task, even if the variable length decoder has stopped on the picture start code of the next picture to be decoded. This is because the picture start code could have been stored in the variable length decoder input FIFO at the end of the previous picture decode and this FIFO is flushed before starting the next decoding task.

The read limit to be programmed must be enlarged by the size of one burst, that is 128 bytes. This is due to internal pipeline processing in the variable length decoder. When the variable length decoder FIFO is empty, there is still about 64 bytes in the variable length decoder pipeline that are not processed.

22.5.4 Error recovery

Confidential

There are three levels of error detection in the video decoder:

- bitstream syntax/semantic error detection with automatic missing macroblocks concealment,
- pipeline underflow error detection,
- pipeline overflow error detection.

Syntax and semantic error detections

The variable length decoder detects the syntax and semantic errors listed below. The way to conceal errors is different depending on the detected errors. The Table 67 describes errors that are detected by the MPEG video decoder. The way to conceal is described after the table.

Layer	Description	Concealment	MBE ¹							
Syntax error: A variable leng	Syntax error: A variable length code which does not exist in the tables or a fixed length code with a forbidden value									
Slice	<pre>quantizer_scale_code = 0</pre>	Previous quantizer_scale_code is used (macroblock or slice). After a reset (HW, SRS), value is set to 1.	N							
Macroblock	macroblock_address_increment	See Procedure 1 on page 199	Yes							
	macroblock_type	See Procedure 1 on page 199	Yes							
	<pre>frame_motion_type and field_motion_type: the value 00 is reserved</pre>	See Procedure 1 on page 199	Yes							
	quantiser_scale_code	Previous quantizer_scale_code (slice or macroblock) is used. After a reset (HW, SRS), value is set to 1.	No							
	marker_bit	See Procedure 1 on page 199	Yes							
	coded_block_pattern_420	See Procedure 1 on page 199	Yes							
	end_of_macroblock for D pictures: it shall be equal to 1.	See Procedure 1 on page 199	Yes							
	motion_code[r][s][t]	See Procedure 1 on page 199	Yes							
Block	first_dct_coef	See Procedure 1 on page 199	Yes							
	next_dct_coef	See Procedure 1 on page 199	Yes							

Table 67: Error detection

Table 67: Error detection

Layer	Description	Concealment	MBE ¹
Semantic error The way of en	ors: coding slices and macroblocks does not fo	llow MPEG rules.	
Slice	Slice start code combined with macroblock address increment gives a macroblock number already decoded.	See Procedure 1 on page 199	Yes
Slice	Slice start code combined with macroblock address increment gives a macroblock number higher than the macroblock number to be decoded.	See Procedure 2 on page 200	Yes
Macroblock	mb_addr_increment may result in a macroblock address greater than the picture size. The macroblock is outside the picture.	See Procedure 2 on page 200	Yes
	The processing of the different parameters in motion_vectors(s) may result in a motion vector outside the reference picture.	If bit MVC in VID_TIS is one, the vector is clipped to point in the picture area. Else, a prediction out of the reference picture is done.	No
	QFS[0] may not lie in the range 0 to ((2^(8+intra_dc_precision))-1).	If negative value, the coefficient is set to 0 but the predictor remains negative	No
Block	Too many coefficients may be found in a block.	See Procedure 1 on page 199	Yes

1. When MBE is yes, the error is taken into account in VID_MBEn registers. When no, the error is not taken into account.

Procedure 1

If the variable length decoder detects a syntax or semantic error in the bitstream, the pipeline copies macroblocks from the previous picture. It uses the motion vectors reconstructed for the previous row of macroblocks in the current picture, and scans the bitstream until a slice start code is detected. At this point, normal decoding resumes.

If the error occurred in the last slice in the picture, concealment continues until the end of the picture. The pipeline then stops normally, assuming that the following picture start code is intact. Macroblocks are concealed using the vectors of the macroblock immediately above the lost macroblock.

Concealment macroblocks are accessed using the forward and backward reference frames. Lost macroblocks in the first row are copied directly from the previous pictures, that is as P-macroblocks with zero motion vectors. If an intra macroblock is coded with concealment motion vectors, the concealment motion vectors are used. If not, concealment is a simple copy from the previous picture using zero vectors.

Table 68 shows the rules used to fetch concealment macroblocks. Skipped macroblocks are not mentioned since they always refer to one of the prediction types listed.

Picture structure/ picture type	Prediction type of the macroblock aligned vertically in the row above	Prediction type of the concealed macroblock 1 vector = (H,V)
I,P,B	Intra no concealment	Forward frame (vector = 0)
Frame picture	Intra with concealment	Forward frame (with sent vector)
I, P, B	Intra no concealment	Forward field (vector = 0)
field picture	Intra with concealment	Forward field (with sent vectors)
P frame picture	Forward frame	Forward frame (with same vectors)
	Forward field	Forward field (with same vectors)
	Dual	Forward field (with vectors of same field parity, that is vectors sent)
P field picture	Forward field	Forward field (with same vectors)
	16x8	Forward field (with same top vectors)
	Dual	Bidirectional field (with same vectors).
B frame picture	Forward frame	Forward frame (with same vectors)
	Forward field	Forward field (with same vectors)
	Back frame	Back frame (with same vectors)
	Back field	Back field (with same vectors)
	Bidirectional frame	Bidirectional frame (with same vector)
	Bidirectional field	Forward field (with same forward vectors)
B field picture	Forward field	Forward field (with same vectors)
	Forward 16 x 8	Forward field (with same top vectors)
	Back field	Back field (with same vectors)
	Back 16 x 8	Back field (with same top vectors)
	Bidirectional field	Bidirectional field (with same vectors)
	Bidirectional 16 x 8	Forward field (with same top vectors)
		1

Table 68: Macroblock type recovery in case of error concealment.

Procedure 2

When the decoder detects that the input stream is not compliant with the restricted slice structure, the decoder reconstructs missing macroblocks by copying macroblocks from the forward reference picture with a null motion vector using frame prediction in a frame picture and field prediction in a field picture.

The decoder detects a nonrestricted slice structure when the slice start code combined with the first macroblock address increment gives an absolute address which is higher (+2 at least) than the previous decoded macroblock number. The decision (restricted or nonrestricted slice structure) is taken on the first macroblock following the slice start code.

An underflow occurs when the last slices are missing and a different start code to a slice start code or an error start code is detected. Missing macroblocks are reconstructed if RMM in $VID_TIS = 1$ and are not reconstructed if RMM = 0. Underflow errors the underflow flag in the status register is always set.

Overflow or underflow error

An overflow error occurs when the variable length decoder detects more macroblocks in the bitstream than the number corresponding to the picture size, VID_DFS. The variable length decoder stops processing macroblocks and resumes a start code search on the next picture start code. Then, it returns in idle state. The overflow condition is flagged by the bit DOE in (VID_STA).

An underflow error occurs when the variable length decoder has found in the bitstream less macroblocks than the number defined by the decoded picture size, VID_DFS and when it stops on a picture start code. Then, it returns in idle state. The underflow condition is flagged by the bit DUE in VID_STA.

The number of macroblocks reconstructed in memory is equal to VID_DFS if RMM in $VID_TIS = 1$ (missing macroblocks are concealed) or to VID_VMBN if RMM = 0 (missing macroblocks are not concealed).

22.5.5 Error statistics

The number and the location of the errors in the pictures determine whether the picture is to be displayed. The decoder gives statistics in the VID_MBEn (macroblock errors) registers. The VID_MBEn registers give the locations of both semantic and syntax errors in the picture. These registers are stable at the end of the decoding task until the start of the next picture decoding task whatever the video channel. At the end of picture decoding, if at least one error occurred during picture reconstruction, bit MSE in VID_STA is set. If no error occurred, this bit is 0.

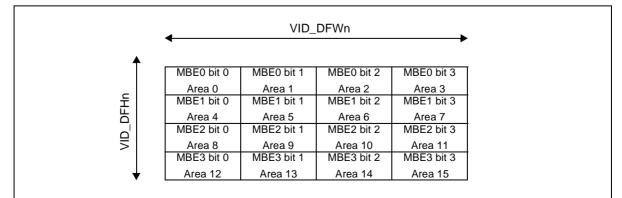

The decoded picture is divided into 16 areas defined by four horizontal and four vertical slides. The areas are numbered from 0 (top left area) to 15 (bottom right). This number is incremented from left to right, top to bottom (Figure 59). For each area, VID_MBEn gives the number of macroblocks reconstructed with error concealment.

If the picture size in macroblock units is a multiple of 4 in both directions, each of the 16 areas contains the same number of macroblocks DFS>>4. If it is not a multiple of 4 macroblocks, the number of macroblocks in each area is:

```
For i and j in [0..2]:
    area(i*4+j)= (DFH >> 2) * (DFW >> 2) MBs
For i=3 and j in [0..2]:
    area(12+j) = (DFH >> 2 + DFH mod 4) * (DFW >> 2) MBs
For i in [0..2] and j=3:
    area(i*4+3) = (DFH >> 2) * (DFW >> 2 + DFW mod 4) MBs
For i = 3 and j=3:
    area(15) = (DFH >> 2 + DFH mod 4) * (DFW >> 2 + DFW mod 4) MBs
```

Note: In the field picture structure, DFH must be divided by 2.

Figure 59: Macroblock error statistics

22.5.6 Simplified B decoding

Simplified B decoding allows bandwidth consumption to be reduced up to 40% while decoding a B-picture. This is done by converting all bidirectional predictors of B-pictures in forward predictors.

The maximum bandwidth required to decode a B-picture is usually 629.5 Mbit/s, but for simplified B this is equivalent to a P-picture at 384.5 Mbits/s.

This feature has an impact on picture quality, but has no effect on the P dual prime picture.

22.6 Resets

22.6.1 Hardware reset

After a hardware reset, the MPEG video decoder is in an idle state. No processing is done and no request is sent on Type 2 initiator until video decoding is launched.

22.6.2 Software reset

Two software resets are implemented.

- VID_SRS: The reset is active when the CPU writes the least significant byte of the VID_SRS register. Software reset is a synchronous active high reset. It resets:
 - variable length decoder flags: DID, MSE, DOE and DUE in VID_STA,
 - variable length decoder input FIFO controller,
 - error statistic registers: VID_MBE0, VID_MBE1, VID_MBE2 and VID_MBE3,
 - debug registers content: VID_MBNM, VID_VMBN and VID_VLDS (VID_VLDS set to 0x0000 00FF),

After the reset no processing is performed until video decoding is started. The MPEG video decoder is in an idle state.

Software reset has no impact on register contents.

• VID_EXE: has the same effect as software reset (VID_SRS), but it also starts the variable length decoder.

23 MPEG video decoder registers

All registers are reset by HW. HW means hardware reset. Read only registers can also be affected by SRS and EXE, see Section 22.6.2: *Software reset* on page 202 for details.

When registers are read, the value of the reserved bits are 0 unless specified. No register is buffered: write action effect is immediate.

Addresses are provided as the MPEGBaseAddress + offset.

The MPEGBaseAddress is:

0x2050 0000.

Description: This register stores the variable length decoder read limit. When the variable length decoder read pointer reaches VID_VLDRL, reading in the buffer is stopped and the bit VLDRL is set to 1 in the status register. This pointer is defined in 128 bytes unit.

24 2D blitter display engine

The 2D blitter display engine is a software controlled output display generator that can also be used as a CPU accelerator for graphics picture handling. It is a triple-source 2D DMA, with a set of powerful operators.

The 2D blitter display engine retrieves data from the local memory through three input sources, Source 1, Source 2 and Source 3. Sources 1, 2 and 3 are used simultaneously for read/modify/ write operations.

- Source 1 is used for frequent operations such as color-fill or simple source copy. It performs according to the pixel format.
- Source 2 is a general-purpose input to which all operators apply.
- Source 3 is an additional input working concurrently with source 2 to retrieve macroblock formats from memory in a single node.

The processing pipeline is always in ARGB8888 or AYCbCr8888 format whatever the format of the source inputs.

The 2D blitter display engine is software controlled using multiple queues which have a link-list structure. Each node of the link list is an instruction that contains all the necessary information to proceed. The 2D blitter display engine, handles both high and low priority queues, known as composition and application queues respectively. The composition queue is real-time constrained (that is it must be finished during a frame), while application queues are executed in the remaining time.

The 2D graphics processor operates at up to F = 200 MHz clock rate. For each operation involving source 2, the maximum output rate is F Mpixel/s, whatever the pixel depth. This rate is constant except for 2D resizing for downsampling, where it is $F \times \text{Hsf} \times \text{Vsf}$ (horizontal and vertical scaling factors). When source 1 is used in direct-copy mode, the internal bus width is 64 bits and the maximum output rate is 8^*F Mbytes/s.

These values are the maximum performances that the 2D blitter display engine can reach. They suppose that no read/write memory word request has been postponed by the memory arbiter mechanism.

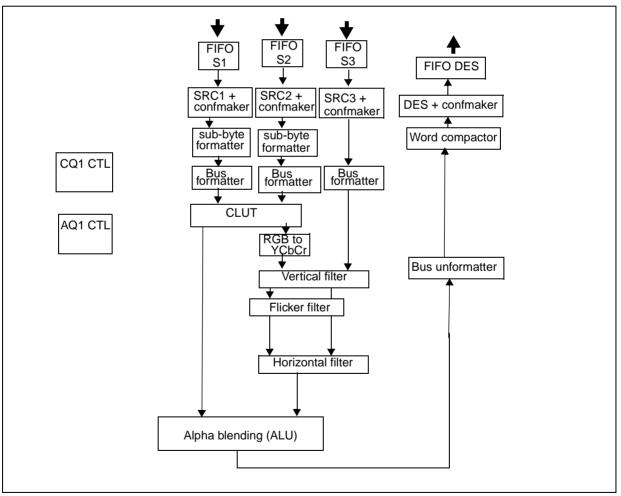

The macroblock format can be used as a source for the 2D graphics engine. Because these formats uses both the source 2 and source 3 buffers, special modes are required. These modes are described in Section 24.7.5: *Using the 4:2:x macroblock-based plane as a source* on page 239.

24.1 2D blitter display engine functions

- Solid color fill of rectangular window.
- Solid color shade (fill + alpha blending).
- One source copy, with one or several operators enabled (color format conversion, 2D scaling).
- Two-source copy with alpha blending.
- 4:2:2 / 4:20 capabilities, as source format.
- Color space conversion RGB to YCbCr (only 601 matrix).
- Color expansion (CLUT to true color).
- Color correction (gamma, contrast, gain).
- 2D resize engine with high quality filtering.
- Fixed coefficient flicker filter from memory to memory.
- Rectangular clipping.
- Programmable source/target scanning direction, both horizontally and vertically, in order to cope correctly with overlapping source and destination area.

The blitter display configuration for the STx5119 is given in Figure 60.

Figure 60: Blitter display

The 2D blitter display engine works from memory to memory with a triple, dual or single source and one target. The target can be one of the sources. A set of overlaps between sources and target are supported, on condition that the pixmap horizontal and vertical scan ordering are

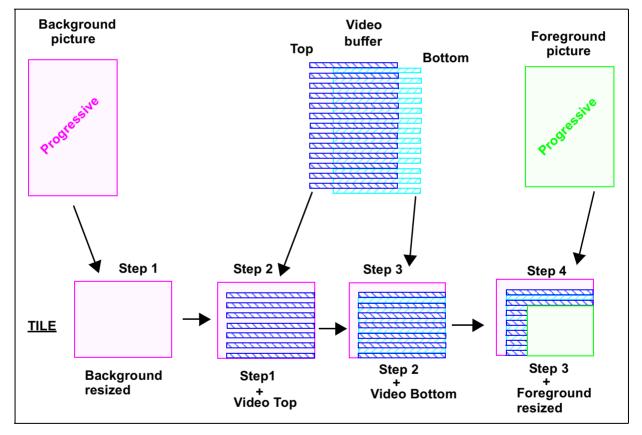

correctly programmed for each source and the target. Each source and target may be programmed independently.

Each source and the target is associated with a specific set of registers. One register (BLT_INS) is used to control the flow of data with operator enables. Each time an operator is enabled, its behavior must be specified with operator specific registers. If the blitter display is not in direct mode (64-bit internal bus), the ALU operator is always enabled and must be programmed.

24.2 Recommended scheme

For best results and to perform clean resizing and filtering on graphics objects, STMicroelectronics recommends processing graphics planes in progressive mode, and processing video input according to whether it is encoded as field- or frame-based data.

This means that a frame buffer (a buffer containing a progressive picture or top and bottom fields interlaced, even if in an interlaced display) is always generated. The GDMA then accesses this buffer with a pitch of 1 or 2 lines depending on whether the display scan style is progressive or interlaced.

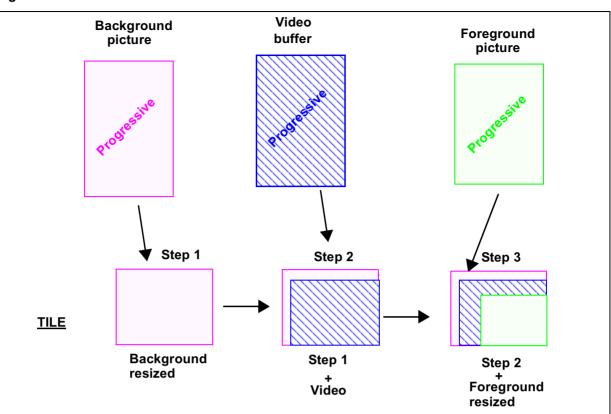

Figure 62: Recommended scheme: frame-based video data

3 Types of source queue

24.3.1 Composition queue (CQ)

The composition queue generates the output display buffer. This queue is high priority. As it is mandatory to render one new frame or field within one frame or field time and to avoid errors on the display, no delay is tolerated. The queue needs to be started on an event (VSYNC, line number, CPU go).

Triggering

Usually, the composition is launched at a specific event. There are three ways of launching a composition queue.

VSYNC

When the 2D blitter display engine is triggered on a VSYNC, it is assumed that the composition linked list was generated during the last frame or field. This provides the maximum amount of time (a full frame or field) to generate (render) the output display buffer VSYNC triggering has a latency between decoding and displaying a picture. In Figure 63 the system has a two frame latency between decode and display.

• Line triggering

Line triggering is the same as VSYNC triggering, except it happens when the VTG line counter reaches the value described in BLT_CQ_TRIG_CTL.TRIG_LINE_NUM. This avoids having another subscriber to the VSYNC event.

In this mode, the system also has a two field or frame latency between decode and display. A line trigger on the first line is not allowed, as it is the same as a VSYNC trigger.

• Soft triggering

In soft triggering the 2D blitter display engine is launched at the most appropriate time by writing to BLT_CQ_TRIG_CTL.TRIG_COND. This is useful where bandwidth is sufficient and a reduced latency is required.

In this configuration, the system has a latency of one field or frame between decode and display, but it introduces more constraints on the composition queue execution time.

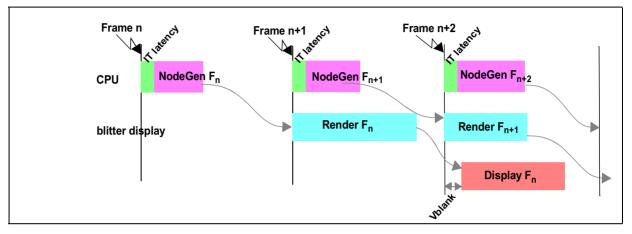

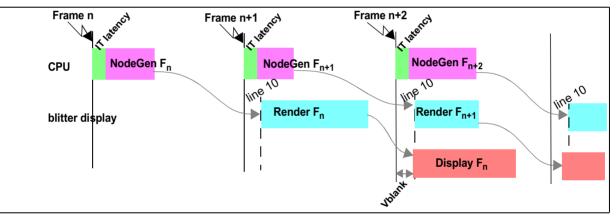

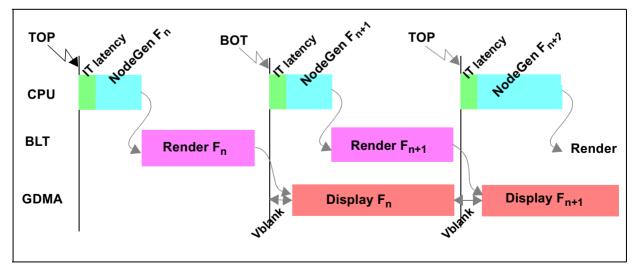

Figure 64: Line number triggering

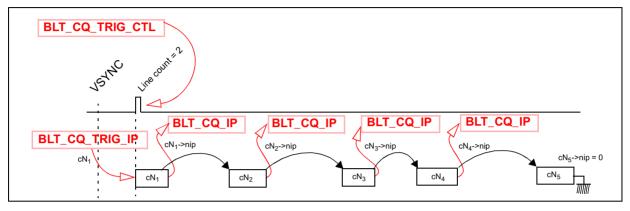

Control

The composition queue is launched when reaching the trigger event (as described in previous section, using the BLT_CQ_TRIG_CTL.TRIG_COND field).

Once this event is met, the blitter fetches the node stored at the BLT_CQ_TRIG_IP address, and starts executing this node and the linked ones. Each time a node is executed, the BLT_NIP register (provided in the node registers) is stored in the BLT_CQ_IP register.

The BLT_CQ_TRIG_IP register provides the absolute start of the queue. It is used only once in a field or frame when the trigger condition is reached. After the trigger, it can be modified any time the composition queue is executing.

Once the blitter reaches NULL BLT_NIP, the composition queue is completed. This queue is then idle until the next triggering event.

Interrupts

There are four interrupt conditions for each composition queue and interrupt status bits are provided in the BLT_ITS register. The CQ associated interrupt line is asserted until the corresponding ITS status bit is cleared by writing 1. See *BLT_ITS* on page 248. All interrupts are maskable through the BLT_CQ_TRIG_CTL.IRQ_MASK field.

• Queue completed

The queue completed interrupt notifies that the display has finished generating and the blitter is now available to process other queues.

Node notification

The node notification interrupt is node based and notifies the level or location of processing within a composition queue. The blitter issues the IRQ when the node has finished executing, but continues processing the queue. The last node that issued the IRQ is shown in the BLT_CQ_IP register.

To issue this IRQ, the blitter must have the BLT_CQ_TRIG_CTL.IRQ_MASK field and the node register (BLT_INS.BLITCOMPIRQ) enabled.

• Queue retriggered

The queue retriggered interrupt occurs when the blitter did not generate the output display (the full composition queue) within the requested time.

If this occurs the actions detailed in the Exception handling section should be taken.

Exception handling

Finish current queue

The blitter executes all the nodes of the gueue seguentially, until it reaches the last node, and then starts executing the next composition queue (pointed by BLT CQ TRIG IP). This assumes that during the time needed for a single composition, the blitter is able to finish both the previous and the current composition. If this recovery succeeds, no errors are seen on the display, but it could also lead to a significant amount of unprocessed data for each field or frame.

Suspend current queue

The blitter executes the current node until it completes, and then jumps to the start of the next composition queue by loading BLT CQ TRIG IP. This allows for a clean drop and restart. It assumes that the retrigger condition will not be reproduced in the next field or frame.

Abort current queue

The current node is executed until the end of the current line, and then jumps to the start of the next composition queue by loading the BLT_CQ_TRIG_IP. This behavior is the same as the previous one, except, it stops as soon as possible to jump to the next queue.

Stop current queue

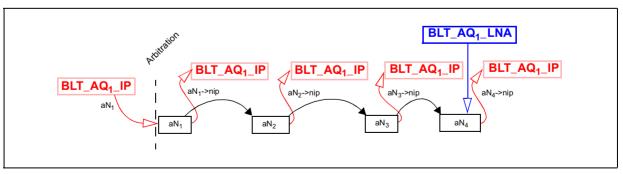

The blitter executes the current node until the end of the current line, and then disables the queue (that is it returns to idle if no other queue is pending). An action is needed to relaunch the composition queue.

Application queues allow the module to be used as a blitter. These queues are of low priority when compared to the composition queue as the nodes are not real-time. Application queues are slave of composition queue execution and are arbitrated together, with programmable priorities.

Application queues (AQ) Application queues allow the when compared to the compo slave of composition queue es **Control** An application queue is launc any time slot not used for con and line trigger in pace down An application queue is launched whenever the composition queue is idle. This means that in any time slot not used for composition, an application queue may be launched between VSYNC and line trigger in pace down time and between composition completion and the next trigger event.

> The application queue is controlled using two pointers: the first node (BLT AQ IP register) and last node pointer (BLT_AQ_LNA register).

Figure 67: Two pointers mechanism for application queues

Using two pointers to handle a single queue allows nodes to be added at the end of the queue without having to interrupt the blitter.

For the new nodes to be taken into account, a new value is written in the last node address register. This implies that the nodes for each application queue are created in a dedicated

memory space, so that the BLT_NIP in the last node is also a valid field (even if the content of next node is not described.)

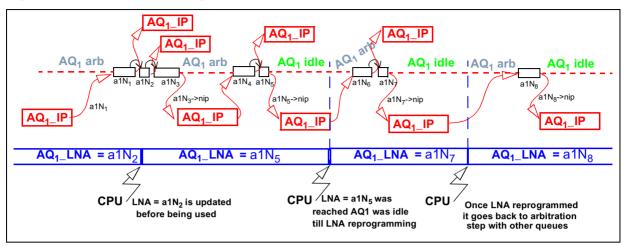

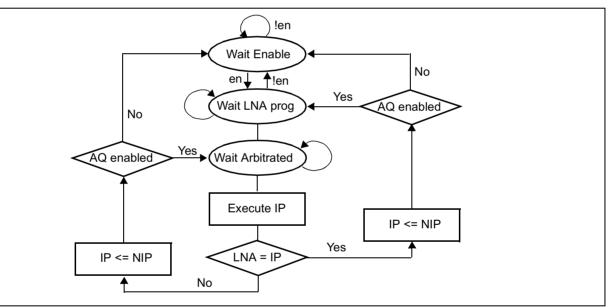

Figure 68: End-of-queue management

The application queue standard behavior is described in Figure 69.

Interrupts

Application queues can provide several types of interrupt, depending upon the condition reached. All these interrupt requests are maskable through the BLT_AQ_CTL.IRQ_MASK field. For each application queue, status bits are provided in the BLT_ITS register, and a register (BLT_AQ_STA) indicating the address of the node which last generated an interrupt request. The application queue associated interrupt line is asserted until the corresponding interrupt status bit is cleared by writing 1 in BLT_ITS. See *BLT_ITS* on page 248.

LNA reached

LNA reached notifies that the application queue has been processed and is now idle. The last node was executed, (BLT_AQ_IP has reached BLT_AQ_LNA) and the queue is now waiting for new nodes to be executed).

Node notification

Node notification notifies the level and location of the processing within a queue. After issuing this interrupt the next node continues to be processed in the queue. The BLT_AQ_STA register shows the address of the last node which generated an interrupt. To issue this interrupt, the BLT_AQ_CTL.IRQ_MASK and the node register BLT_INS.BLITCOMPIRQ must be enabled.

Exception handling

As for the composition queue, application queues are able to support nonstandard behavior.

This allows for efficient, fast queue switching by directing how the application queue hands back to the composition queue.

• Suspend current queue

The node is executed until its end, and then the application queue is released in favor of the requesting composition queue. This behavior does not generate an interrupt, as nothing is stopped or aborted. This is the default behavior, but could lead to some execution time problems, if the application node took too long to finish.

• Abort current queue

This is the fastest solution. The current line is finished and the queue is immediately released in favor of the requesting composition queue. This behavior generates an interrupt (if enabled) as it means that the stopped node is the new starting point for the application queue.

It might be useful to poll the BLT_AQ_STA register to verify that it is not always the same node which is interrupted for each new pace up. This means that the execution time of this application node is too long to be interleaved within a pace interval.

24.3.3 Composition queue and application queue interleaving flow

Figure 70: Queue interleaving without pace

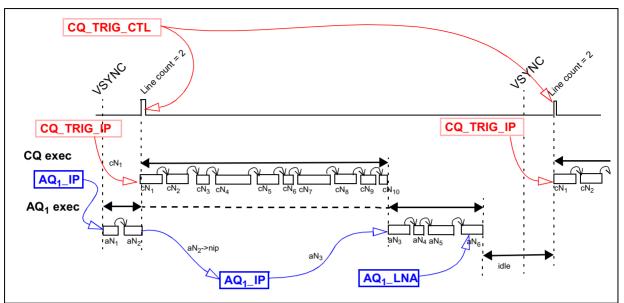

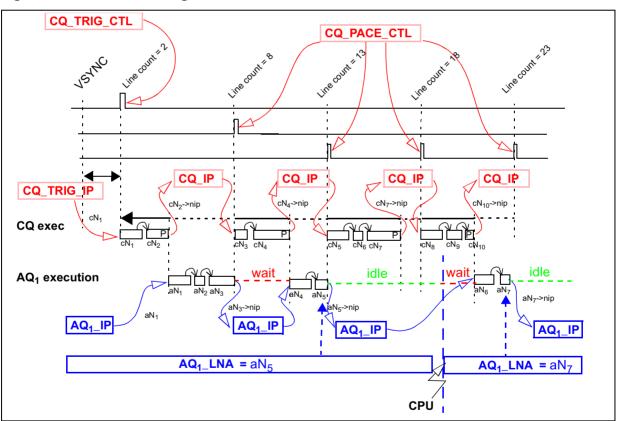

Figure 71: Queue interleaving

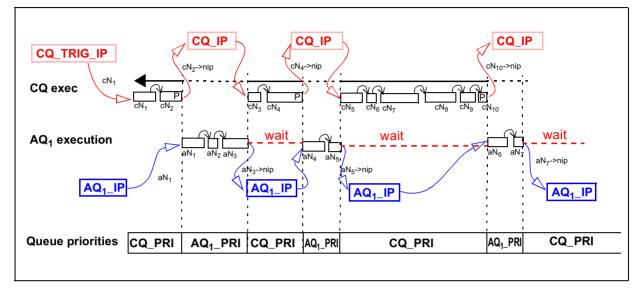

7939391A

Queue priority

A unique priority is set for each queue, by using the fields in the BLT_PRI.CQ_PRI and BLT_PRI.AQ_PRI registers. Generally, the composition queue has a high priority in the system to ensure the composition finishes in the time required, while the application queues have the lower priorities as they are executed in the system idle time.

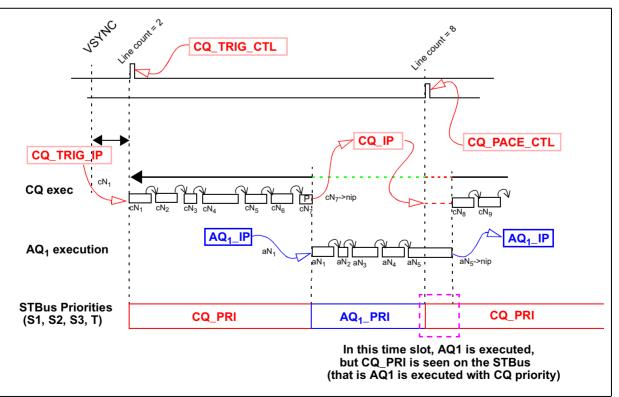

Priority forwarding

When an application queue is executing, and a composition queue is awakened (it is triggered or receives a pace up event), the AQ_PRI is replaced by CQ_PRI, so that the last node(s) to execute in the application queue are executed with the composition queue priority. This mechanism is called priority forwarding.

Figure 73: STBus priority forwarding

24.3.4 Short linked list

As the output display buffer is being composed hundreds of nodes for each field or frame are generated. To save bandwidth short linked-list mode writes a subset of registers for each node. This subset describes the functionality used, and does not write the registers of unused functions. Nodes can therefore vary in length, according to the functions used. This allows short nodes for simple operations, and longer ones for more complex operations.

To enable the required functions for short linked-list mode, set the corresponding bits in the BLT_CIC (current instruction content or node resolution key) register

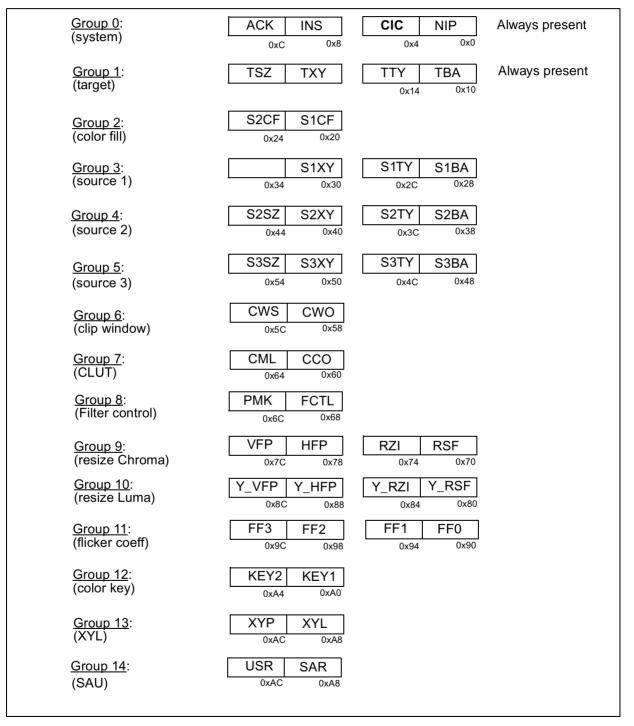

Figure 74: Functional groupings of registers

Functional register groupings are of variable length either 64- or 128-bit width. Only groups 0 and 1 are always present. The groupings depend upon which operation is performed. Unused registers are set to their reset value when the node is loaded.

Decoding the source

24.4.1 Source address generation

Source 2

The source 2 address generator scans a rectangular window, according to a 2D XY addressing scheme. The XY pixel address is converted into a physical memory address, using the source 2 description registers.

Reference formula for address conversion:

```
MemAddress (x,y) = BaseAddress + y *Pitch + x * (NumberOfBytesPerPixel)
```

Register BLT_S2BA is the memory base address of the bitmap selected for source 2 (absolute [0,0] location, top-left pixel).

Register BLT_S2TY provides the properties of source 2:

- format,
- pitch,
- horizontal and vertical scan order,
- sub-byte ordering (for sub-byte formats),
- bit accuracy expansion mode,
- chroma sign (for YCbCr formats),
- chroma features (YCbCr macroblock formats).

Register BLT_S2XY is the co-ordinate that specifies the start of the input source 2 window relative to the base address.

Register BLT_S2SZ specifies the size of the source 2 window.

Source 1

Source 1 is used for frequent operations such as color-fill or simple source-copy.

The source 1 address generator scans a rectangular window, according to an XY addressing scheme. The XY pixel address is converted into a physical memory address, using the source 1 description registers.

Register BLT_S1BA is the memory base address of the bitmap selected for source 2 (absolute [0,0] location, top-left pixel).

Register BLT_S1TY provides the specific properties of source 1: format, pitch, horizontal and vertical scan order, sub-byte ordering (for sub-byte formats), color depth expansion mode.

Register BLT_S1XY is the coordinate that specifies the start of the source 1 input window with respect to the base address.

Register BLT_S1SZ does not exist, as S1 can not be resized, S1 width and height are always equal to target width and height (described in BLT_TSZ).

Source 3

Source 3 is used for macroblock luminance part access only. It is always used in conjunction with source 2 which accesses the chrominance part while source 1 accesses luminance.

The source 3 address generator scans a rectangular window, according to a XY addressing scheme. The XY pixel address is converted into a physical memory address, using the source 3 and source 2 description registers.

Register BLT_S3BA is the memory base address of the luminance block of the bitmap selected for source 3 and source 2 (absolute [0,0] location, top-left pixel).

Register BLT_S3TY provides the pitch of source 3. All other values are retrieved from BLT_S2TY register (COLOR_FORMAT, VSO, HSO) as source 2 and source 3 are always used together when the macroblock format is used.

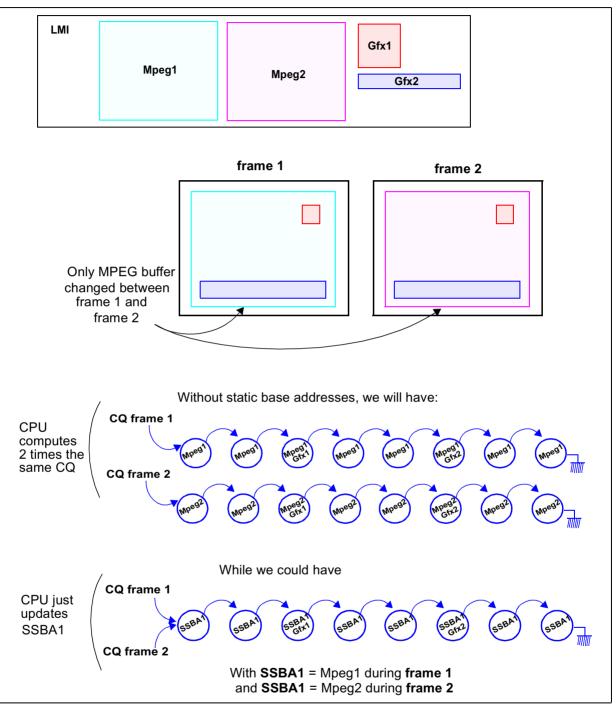

Register BLT_S3XY is the coordinate that specifies the start of the source 3 input window with respect to the base address.

Register BLT_S3SZ specifies the size of the source 3 window.

Static base addresses

When there is no change to display plane position or size the same linked list can be used on several fields or frames to avoid recomputing the full composition queue. Only the base address registers (S1BA, S2BA, S3BA, and TBA) need to change.

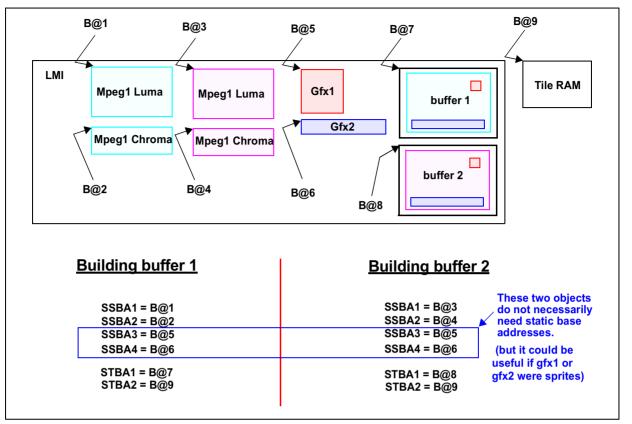

For the static base address, eight registers are shared between the three input sources, and two registers are available for the output target.

Use of the static source base address (SSBA) and the STBA (T for target) is determined in the SAR register.

If the value contained in BLT_SAR.Sn_SSBA equals zero, then the Sn base address is taken from the linked list in the BLT_SnBA register. If the value contained in BLT_SAR.Sn_SSBA is not equal to zero, its value points to the register to be used by Sn as its base address.

The same mechanism is used for the target address, through the STBAn registers.

lote: Static base addresses are available for the composition queue only.

The Number of SSBA and STBA register is scalable depending upon the target device. As this static base addresses register mechanism is intended to save CPU bandwidth, the number of static registers is set according to the target application. For a full list of the available registers see *BLT_SSBAn* on page 250.

Source 2

The source 2 formatter converts a 64-bit input bus into a pixel bus, depending on the current format selected for source 2. The internal pixel bus is 32 bits wide, but a subset of the data is used by many color format modes. All formats are available. The pixel bus format is shown in Table 70.

YCbCr 4:2:2 (first pixel Y- only)	Y 1 ^{rst} pixel		Cb 2 nd pixel		Y 2 nd pixel		Cr 2 nd pixe	əl					

Note: In this last mode no alpha value is produced by the block and the bus carries 2 pixels simultaneously. The alpha channel (128 = opaque) is inserted by the 4:2:2 to 4:4:4 converter (next block in the pipeline). This converter is automatically enabled for this configuration.

When the input picture has an 8-bit per-pixel alpha component, this component can have a 0:128 or 0:255 range. The internal 8-bit alpha format being 0:128, a 0:255 alpha component is converted using the following formula: $A_{0..128} = (A_{0..255} + 1) >> 1$

Source 1

In fast direct-copy mode, the source 1 bus formatter is unused. Rectangular graphics areas are transferred faster, but sub-byte color formats are not supported. The rectangular clipping feature cannot be used.

Each time the 2D graphics engine performs a read-modify-write cycle to combine background information with new data, the source 1 bus formatter converts a 64-bit input bus into a pixel bus, that feeds the ALU operator.

In normal mode, the bus formatter is similar to the one described for source 2, except for YCbCr4:2:2R which is not supported as a source 1 operand. Source 1 data can be combined with source 2 data using the ALU operator.

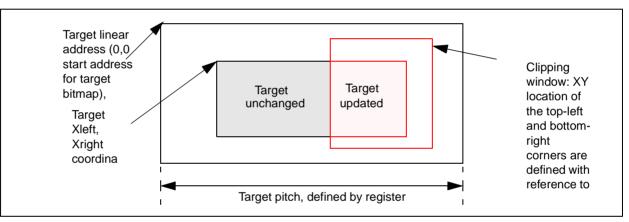

24.5 Clipping

24.5.1 Rectangular clipping

For a rectangular window each write access to the target plane can be enabled on a pixel-perpixel basis.

The base address of the 2D graphics engine is in x-y coordinates. Hardware clipping uses four registers to define the rectangular clipping area. Figure 78 shows a block transfer operation inside a buffer, using a hardware clipping window. The buffer is defined using a linear start address. The display area and the clipping window are defined by x-y coordinates. The display function is only valid inside the clipping window.

Figure 78: Hardware clipping window

Configuration bit BLT_CWO.INTNL inverses the clipping window. The target area is updated outside the clipping window and is protected inside the clipping window.

Register bits BLT_CWO.XDO and BLT_CWO.YDO define the target base address for the start of the window.

Register bits BLT_CWS.XDS and BLT_CWS.YDS define the target base address for the window end.

24.6 Color operations and conversion

24.6.1 RGB to YCbCr conversion

Graphic matrix

Converting from RGB to YCbCr the Y component is clipped between 16 and 235, after applying the matrix. The chroma range is -112/+112, and can be optionally encoded in offset-binary format (+128, 16/240 range).

- BLT_CCO.CCO_INCOL sets the input color converter colorimetry (601).
- BLT_CCO.CCO_INSIGN sets the input color converter chroma color sign.
- BLT_CCO.CCO_INDIR sets the input color converter direction (RGB to YCbCr).

Table 74 to Table 75 show the hard wired matrices used for the conversion (assuming offset binary chroma)

Table 74: 601 colorimetry / floating-point matrix / digital range

RGB to YCbCr reference	floating-point matrix
-------------------------------	-----------------------

Y	=		0.257	xR	+	0.504	xG	+	0.098	хB	+	16
Cb	=	-	0.148	xR	-	0.291	xG	+	0.439	xВ	+	128
Cr	=		0.439	xR	-	0.368	xG	-	0.071	xВ	+	128

Y	=		263	xR	+	516	xG	+	100	xВ	+	16
Cb	=	-	152	xR	-	298	xG	+	450	xВ	+	128
Cr	=		450	xR	-	377	xG	-	73	xВ	+	128

Video matrix

Converting from RGB to YCbCr the Y component is clipped between 1 and 254, after applying the matrix. The chroma range is -127/+126, and can be optionally encoded in offset-binary format (+128, 1/254 range).

- BLT_CCO.CCO_INCOL sets the input color converter colorimetry (601).
- BLT_CCO.CCO_INSIGN sets the input color converter chroma color sign.
- BLT_CCO.CCO_INDIR sets the input color converter direction (RGB to YCbCr), and the output color converter is automatically programmed with the other direction.
- BLT_CCO.CCO_INGFXnVID sets the input color converter to graphic or video matrix.

Table 76 to Table 77 shows the hard-wired matrices used for the conversion (assuming offset binary chroma).

Table 76: 601 colorimetry / floating-point matrix / digital range

RGB to YCbCr reference floating-point matrix

Y	=		0.2988	xR	+	0.5869	xG	+	0.1143	xВ

Y	=	306	xR	+	601	xG	+	117	xВ	+	
Cb	= -	177	xR	-	347	xG	+	523	xВ	+	128
Cr	=	523	xR	-	438	xG	-	85	хB	+	128

24.6.2 Color expansion

During color expansion a CLUT-based bitmap is transformed into a true-color bitmap, using the embedded look-up-table (256 x 32 SRAM). Figure 79 illustrates a CLUT-to-RGB conversion and Figure 80 a CLUT88/44-to-RGB conversion.

In a CLUT-to-RGB conversion:

- CLUT entries can be color-corrected if required (for example gamma, contrast),
- with a CLUTn input, only the first 2ⁿ addresses need to be initialized,
- the CLUT always outputs an alpha channel, whatever the input format,
- if the CLUT module is enabled, the 2D graphics engine instruction contains a pointer to the CLUT local memory location,
- in some specific applications, the CLUT entries can be YCbCr encoded. The memory/bus correspondence between the two color spaces is R/Cr, G/Y, B/Cb.

Figure 79: ACLUTn to (A)RGB conversion

CLUT-	Embedded	True-
	Alpha LUT 256x8 SRAM (2n used)	► Alpha / 8 bits 0:128
CL	Red LUT 256x8 SRAM (2n used)	► R / 8 bits 0:255
UT-	Green LUT 256x8 SRAM (2n used)	► G / 8 bits 0:255
	Blue LUT 256x8 SRAM (2n used)	► B / 8 bits 0:255

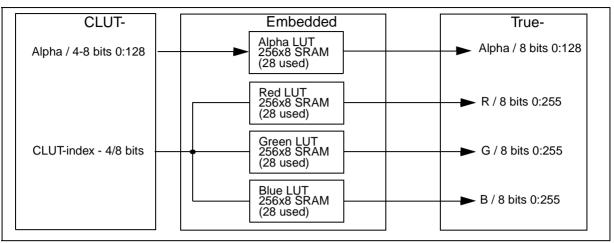

In a CLUT88/44-to-RGB conversion:

- CLUT entries can be color-corrected if required (for example gamma, contrast),
- The CLUT always outputs an alpha channel, whatever the input format,

• In some specific applications, the CLUT entries can be YCbCr encoded. The memory/bus correspondence between the two color spaces is R/Cr, G/Y, B/Cb.

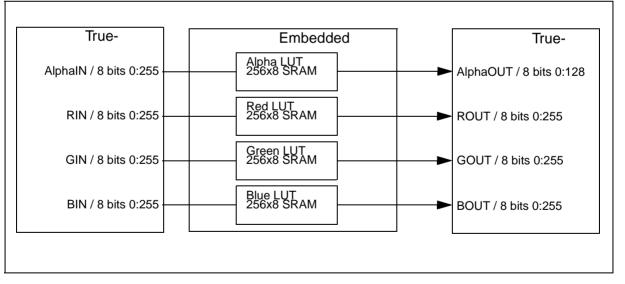

Note: Color expansion is performed exclusively on either source 1 or source 2.

24.6.3 Color correction

The CLUT can be used as four independent 256 x 8 LUTs, applying any transformation on the input components. This can be used for gamma correction, contrast adjustment, gain, offset. Used in conjunction with the 2D graphics engine color space converters (at the input and the output), the correction can also be made in the YCbCr space (color effect, conversion to a gray-scale bitmap).

Register BLT_CML is a pointer to the local memory CLUT address. Register bit BLT_CCO.CLUT_UPDATE enables CLUT refresh from memory. Register bit BLT_CCO.CLUT_MODE sets the CLUT mode: color expansion and color correction. *Color correction is performed exclusively on either source 1 or source 2.*

Note:

24.6.4 Color fill

Registers BLT_S1CF and BLT_S2CF provide the solid color value for filling during an operation. BLT_S1CF allows the direct fill mode to be used for faster performance.

The number of significant bits varies from 1 bpp to 32 bpp according to the bit depth of the color format.

Color fill is supported for all color formats except for macroblocks.

Direct fill and direct copy modes

These modes are used on source 1 only. They allow the output bit rate to be doubled compared to simple copy or fill operations such as rectangle fill and rectangle move. The data is not interpreted when copying.

Note: Only raster formats are supported.

To perform in direct fill or direct copy mode source 1 should be enabled and sources 2 and 3 (and their associated operators) disabled. The target and source 1 should have the same data format and the same vertical and horizontal pixel scan order. In direct fill mode the scan order should be top-to-bottom and left-to-right (that is S1TY_HSO and S1TY_VSO are equal to 0.)

24.7 2D resizing and filtering

24.7.1 Overview

The 2D resize engine is composed of four sub-blocks: a vertical source, a horizontal source, a context-sensitive flicker filter and a deinterlacer. It is illustrated in Figure 82.

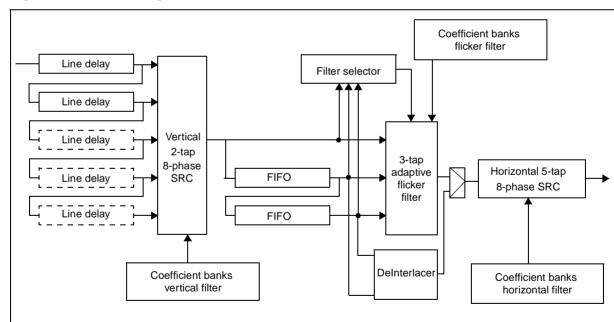

Figure 82: 2D resize engine overview

24.7.2 Vertical filter

The vertical filter is a 2 taps polyphase filter, based on a 6.10 bit sample rate converter. It uses the upper 3-bits of the decimal part to give eight subpositions. Thus it has eight sets of two coefficients subposition based. The vertical filter can be used in two ways depending upon the input format. For all raster formats, it operates as a single device applying the same filter on all the components (A, R, G an B) provided by source 2. For all macroblock formats, it becomes two

separate filters, applying different coefficients and resize factors on two separate paths: the luminance and chrominance path (source 3 and source 2).

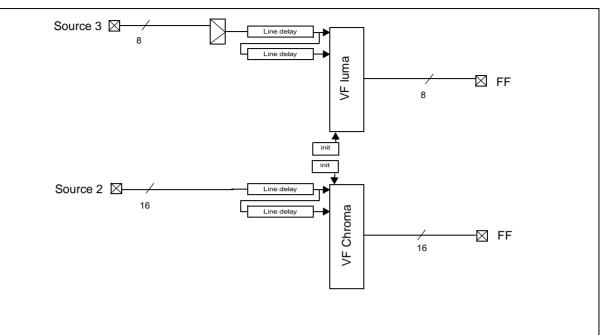

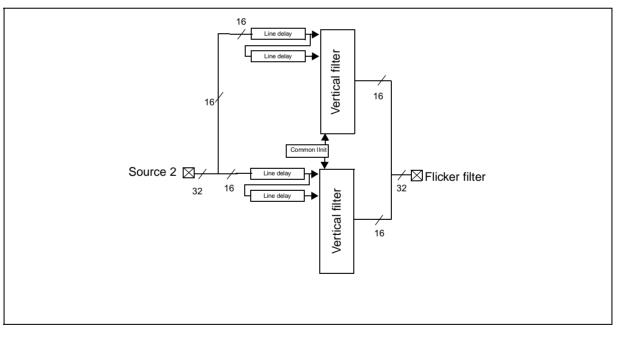

Figure 84: Vertical filter in raster mode

To use the vertical filter in raster mode and initialize the filter, set:

- the initial subposition in BLT_RZI.VSRC_INIT,
- the resizing factor in the BLT_FCTL.VSRC_INC field.

These input values are used by both paths if the blitter display deals with raster formats.

To use the vertical filter in 4:2:0 macroblock mode and initialize the filter, set:

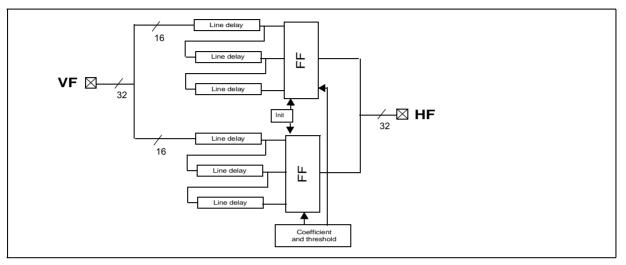

- two initial subpositions in BLT_RZI.VSRC_INIT and BLT_Y_RZI.VSRC_INIT,
- the resizing factor needs to be set in the BLT_RSF.VSRC_INC and BLT_Y_RSF.VSRC_INC fields.

Vertical filter programing in macroblock format is detailed in Section 24.7.5: Using the 4:2:x macroblock-based plane as a source on page 239.

Note: When the input format is 4:2:0 macroblock, the two luma and chroma paths will not provide the same amount of data. The chroma path therefore needs to be upsampled by two.

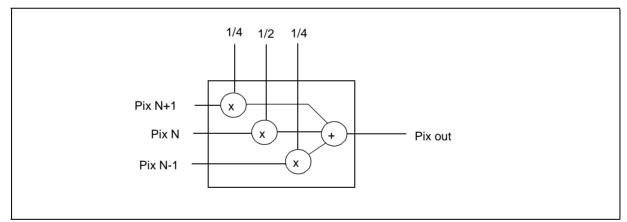

24.7.3 Fixed coefficient flicker filter

Figure 85: Flicker filter block diagram

The flicker filter is a 3-tap filter, and applies a simple flicker algorithm: 1-2-1.

Figure 86: Flicker filter 1-2-1 data path

24.7.4 Horizontal filter

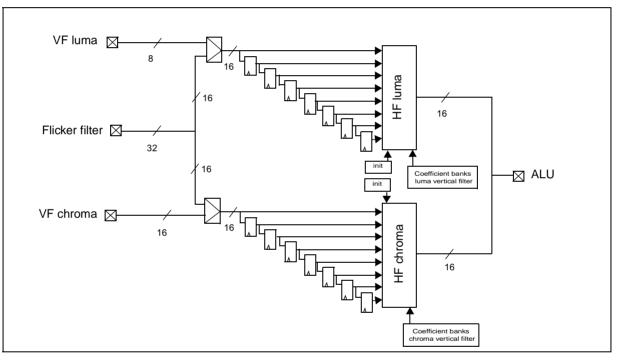

The horizontal filter is an 8-taps polyphase filter, with a 3-bit subposition (eight values), with eight sets of eight coefficients. The horizontal filter data path is based on a 6.10 sample rate converter, which first upsamples the incoming pixels, and applies the subposition selected filtering coefficients on the samples (if enabled) to generate output pixels.

Like the vertical filter, the horizontal filter can be used in two distinct forms depending upon input format:

- a single device for all raster input formats,
- as two separate filters, applying different coefficients and resize factors on two separate paths for the 4:2:0 macroblocks format.

When in 4:2:0 macroblock formats, chrominance also needs to be horizontally upsampled so fewer chroma samples than luma samples are received. The vertical filter data path needs to be split in two separate and independent paths, with different rescale factors, initialization, and coefficients.

Figure 87: Horizontal filter block diagram

Depending on the data processed by the horizontal filter, there could be two different views as shown in Figure 88.

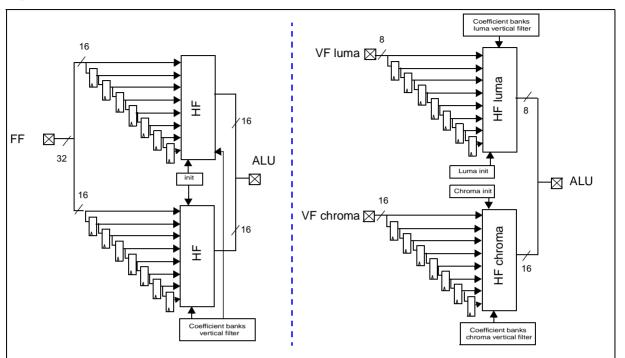

Figure 88: Horizontal filter raster and macroblock modes

To use the horizontal filter in raster mode

To initialize the filter, set:

Confidential

- the initial subposition in BLT_RZI.HSRC_INIT,
- the number of times the first pixel needs to be repeated to deal with filter startup in BLT_RZI.HNB_REPEAT,
- the resizing factor in the BLT_RSF.HSRC_INC.

These input values are used by both paths if the blitter display deals with raster formats.

To use the vertical filter in macroblock mode.

To initialize the filter set:

- two initial subpositions in BLT_RZI.HSRC_INIT and BLT_Y_RZI.HSRC_INIT,
- the number of time the first line needs to be repeated to deal with filter startup in BLT_RZI.HNB_REPEAT and BLT_Y_RZI.HNB_REPEAT.
- the resizing factor needs to be set in the BLT_RSF.HSRC_INC and BLT_Y_RSF.HSRC_INC.

Horizontal filter programing in macroblock format is detailed in Section 24.7.5.

24.7.5 Using the 4:2:x macroblock-based plane as a source

Because chrominance data in macroblock format is compressed, one luma sample does not necessarily have a corresponding chroma sample. As the ALU processes in 4:4:4 format, chroma samples must be upsampled prior to use.

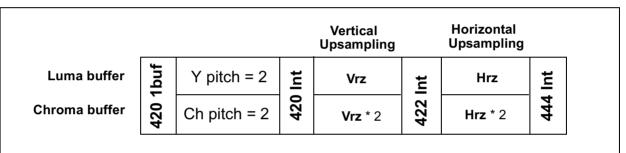

The simplest and cleanest way to upsample chrominance is to use the horizontal and vertical filters. The programming of the filters varies according to the content encoding style and the display style.

The vertical and horizontal filters and resizers are enabled as follows.

- BLT_FCTL.2DHF_MODE = horizontal filter active on both color and alpha,
- BLT_FCTL.2DVF_MODE = vertical filter active on both color and alpha,
- BLT_FCTL.LUMA_2DHF_MODE = both luma horizontal resizer and horizontal filter active,
- BLT_FCTL.LUMA_2DVF_MODE = both luma vertical resizer and vertical filter active.

Note: In the next sections, Vrz and Hrz stand for the vertical and horizontal resize factors. If no resize other than a chroma upscale is applied, these are equal to 1. The increment value programmed in the XXX_INC registers is 1/Vrz and 1/Hrz.

Figure 89: Content interlaced, display interlaced

For content interlaced with display interlaced modes the 2D blitter display engine is programmed as below.

BLT_S2BA = chroma base address (or B@ + pitch depending field)

BLT_S2TY.PIXMAP_PITCH = chroma pitch

BLT_S2TY.COLOR_FORM = 4:2:0 MB

BLT_S2TY.MB_FIELD = field

BLT_S3BA = luma base address (or B@ + pitch)

BLT_S3TY.PIXMAP_PITCH = luma pitch

BLT_S3TY.MB_FIELD = field

BLT_RSF.VSRC_INC = 1 / Vrz

24.8 Blending operations

24.8.1 Output unformatting

The output bus unformatter transforms the internal ARGB8888 or AYCbCr8888 32-bit bus in the output pixel format bus.

Table 78: Target unformatter o	output
--------------------------------	--------

Output	Alpha	Color data		
format	31:24	23:16	15:8	7:0
ARGB8888	A[7:0] or expand	R[7:0]	G[7:0]	B[7:0]
RGB888	N/A	R[7:0]	G[7:0]	B[7:0]
ARGB8565	A[7:0] or expand	R[7:3]+0.5 or dither	G[7:2]+0.5 or dither	B[7:3]+0.5 or dither
RGB565	N/A	R[7:3]+0.5 or dither	G[7:2]+0.5 or dither	B[7:3]+0.5 or dither
ARGB1555	A[8]	R[7:3]+0.5 or dither	G[7:3]+0.5 or dither	B[7:3]+0.5 or dither
ARGB4444	A[6:3] 0xF if128, 0x0 kept	R[7:4]+0.5 or dither	G[7:4]+0.5 or dither	B[7:4]+0.5 or dither
A1	A[7]	N/A	N/A	N/A
A8	A[7:0] or expand	N/A	N/A	N/A
AYCbCr8888	A[7:0] or expand	Cr[7:0]	Y[7:0]	Cb[7:0]
YCbCr888	N/A	Cr[7:0]	Y[7:0]	Cb[7:0]

2 x 2 dithering avoids leveling the output picture when reducing the output dynamic (reducing from 8 bits). It consists of introducing pseudorandom noise on the lower levels of decimated color.

The dither algorithm is:

 $DitherPattern = (Ypos and 0x1) + (((Xpos and 0x1)^{(Ypos and 0x1)}) << 1)$

Then (example for a RGB565 output)

r = r[7:0] + *DitherPattern*<<1; R =r >>3

g = g[7:0] + DitherPattern; G = g >> 2

b = b[7:0] + *DitherPattern*<<1; B =b >>3

This dither mechanism is enabled by setting the BLT_TTY.RGB_ROUND bit.

The alpha can be stored in the 128 to 0 or 255 to 0 range by setting the

BLT_TTY.ALPHA_RANGE bit. Internal processing is done in 128 to 0 mode, so when this bit is set, the alpha channel is expanded as follows:

 $Alpha_{255} = ((Alpha_{128} - 1) << 1) + 1$

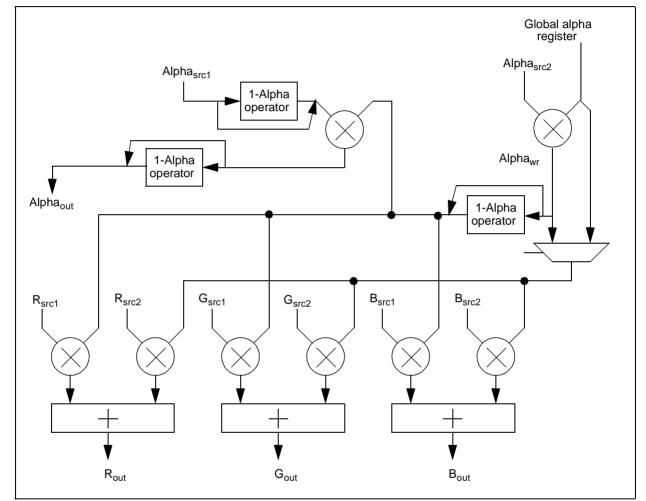

24.8.2 Alpha blending

The alpha blender interpolates colors between source 1 and source 2 (see Figure 93.)

Each source may have its own per-pixel alpha component. Source 2 is always blended on top of source 1. Source 1 is usually the source for the background plane. Source 1 and 2 are blended using their own alpha, combined with register bit BLT_ACK.GALPHA (global alpha register).

Source 2 supports alpha premultiplied or nonalpha premultiplied color formats (premultiplied ARGB formats are AR, AG and AB). The multiplexor is necessary to select between Alpha_{wr} and the global alpha register.

Blending equations are given in Figure 94.

Figure 94: Blender reference equations

If Src2 is not pre-multiplied:
$\mathbf{RGB}_{\mathbf{out}} = \operatorname{Asp}(2 \xi \Gamma \lambda \circ \beta \alpha \lambda_A \lambda \pi \eta \alpha_P \varepsilon \gamma \operatorname{Istep} \xi P \Gamma B \sigma \rho \chi 2 + (1 - A \sigma \rho \chi 2 \xi \Gamma \lambda \circ \beta \alpha \lambda_A \lambda \pi \eta \alpha_P \varepsilon \gamma \operatorname{Istep}) \xi$
ΡΓΒσρχ1
If Src2 is pre-multiplied:
$\textbf{RGB}_{out} = \Gamma \lambda o \beta \alpha \lambda_A \lambda \pi \eta \alpha_P e_{\gamma oter} \xi P \Gamma B \sigma p \chi 2 + (1 - A \sigma p \chi 2 \xi \Gamma \lambda o \beta \alpha \lambda_A \lambda \pi \eta \alpha_P e_{\gamma oter}) \xi P \Gamma B \sigma p \chi 1$
In any case, the resulting translucency is:
$(1 - A\lambda\pi\eta \alpha out) = (1 - Aspc2 \xi \Gamma \lambda bbal A\lambda\pi\eta a Perister) \xi (1 - Aspc1)$
This is equivalent to:
Αλπηαουτ = Ασρχ2 ξ Γλοβαλ_Αλπηα_Ρεγιστερ + Ασρχ1 ξ (1 – Ασρχ2 ξ Γλοβαλ_Αλπηα_Ρεγιστερ)
or Alphaout = Asrcl + Asrcl ξ Global_Alpha_Register ξ ($1 - Asrcl)$

The Alpha_{out} component is written into the target bitmap, only if the target format includes a perpixel alpha component.

Note: When a target format has a perpixel alpha component the color components RGB_{out} are computed as premultiplied by this alpha value. The display pipeline is aware of this when blending a 2D-graphics layer with the video layer.

A third source can be blended with sources 1 and 2, to create a single output. The third source must be a 1 bpp or 8 bpp bitmap mask. This three source blending is implemented in two stages:

- 1. The texture (or foreground picture) uses the source 1 pipeline, and the third source (bitmap mask) uses the source 2 pipeline. They are combined into an intermediate bitmap (that must have a per-pixel alpha component, for example: ARGB8888).
- 2. The intermediate bitmap uses the source 2 pipeline and the background picture uses the source 1 pipeline. They are blended together.

25 2D blitter display engine registers

Addresses are provided as the BDispBaseAddress + offset.

The BDispBaseAddress is:

0x2100 0000.

Description: This register gives the XY location of the first pixel to be transferred, with reference to the top-left corner of the source 2 bitmap (0,0). This XY location depends on the programmed horizontal and vertical scan order (register BLT_S2TY).															
Note:	In XYL standard mode, this register contains the 2D-vector that gives the location of the (0,0) clipmask value, with respect to the (0,0) pixel location of the target bitmap. Bits[15:0] provide the horizontal offset, bits[31:16] provide the vertical offset (both values are 16-bit signed integers).														
	In XYL transform mode, this register is unused.

Description:

26 TV out

26.1 Overview

The TV out module processes the YCbCr 444 video and graphics data in memory to provide the following digital video outputs.

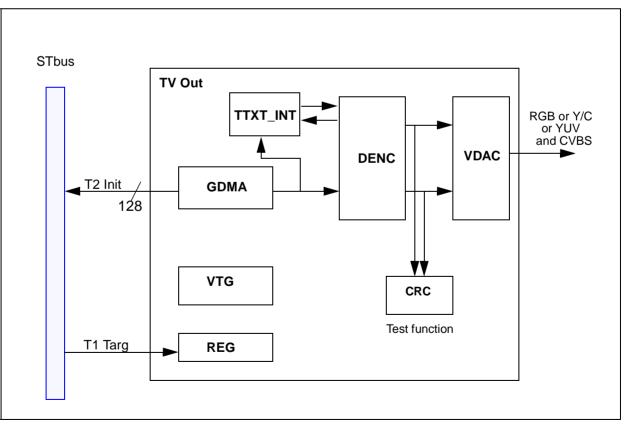

- PAL/NTSC/SECAM encoding with color control processing.
- Macrovision 6.1/7.01 copy protection, enabled/disabled by external anti-fuse.
- Teletext re-insertion in vertical blanking interval.
 - VBI WSS, DVB teletext.
 - VBI closed caption for CMGS-A transmission.
- 10-bit quad video DAC to output the following combinations.
 - CVBS + RGB or YUV.
 - S-VHS(Y/C) + CVBS + CVBS.

All video outputs have the same video content.

The TV out subsystem integrates the DENC, DAC, VTG, TTXT_INT and GDMA. Figure 95 shows the video and graphics dataflow for the STx5119 from memory to output. The process is controlled by the video timing generator (VTG) that provides video synchronization signals to the TV out submodules and to the blitter and CPU.

e: As shown in Figure 97: TV out block diagram on page 277, the DENC DAC6 is connected to the video DAC4 output.

Figure 95: TV out architecture

Confidential Note: The following submodules are integrated into the TV out block:

- graphics DMA, see Chapter 28: Graphics DMA (GDMA) on page 282,
- digital encoder, see Chapter 30: Digital encoder (DENC) on page 293,
- video timing generator, see Chapter 32: Video timing generator (VTG) on page 352,
- video DAC,
- Teletext Interface (TTXT_INT) see Section 26.2: Teletext on page 278.
- CRC

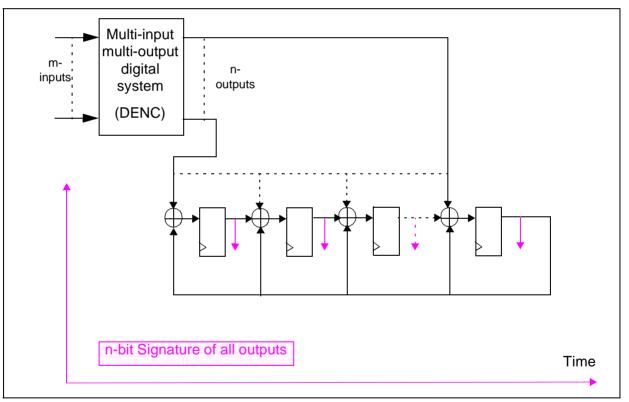

The CRC block is used for compression of the digital output response. The general structure of a CRC is shown in Figure 96. The CRC is an internal-XOR type 24-bit polynomial:

$$g(x) = x24 + x23 + x22 + x17 + 1$$

There is a 10-bit input CRC circuit for each of the four channel outputs. The 4 x 24-bit signatures at the end of each test are compared with reference good signatures and the status register reflects whether the test has passed or failed.

The signature computation, when enabled, starts after the next Vsync active edge and stops after one full frame has been captured. Subsequently, the CRC block can be reset and another one frame of data can be tested.

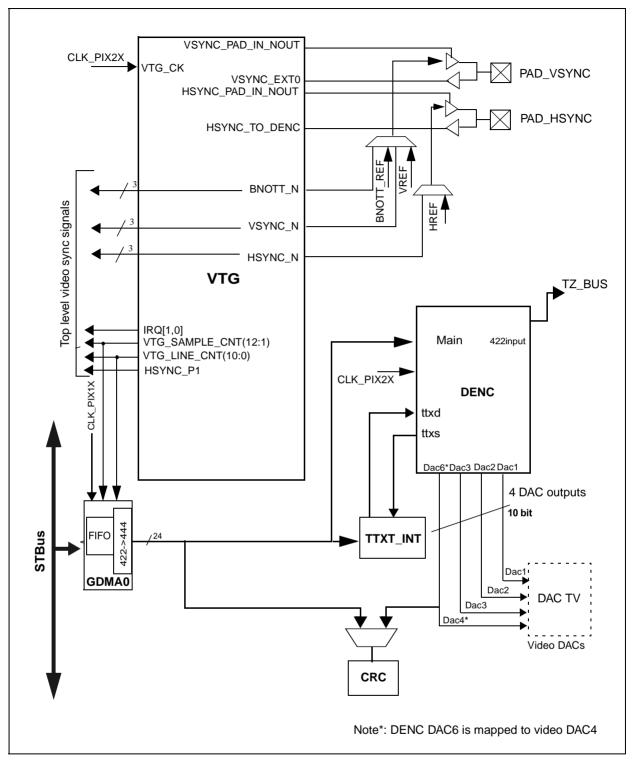

Figure 96: CRC: General Structure

External to TV out, the blitter engine scales and converts the MPEG decompressed video data and writes the processed active video and graphic data to the external memory in YCrCb format.

7939391A

Figure 97: TV out block diagram

26.2 Teletext

Teletext data is retrieved from memory, serialized and transferred to the digital encoder. The digital encoder encodes teletext data according to the CCIR/ITU-R Broadcast Teletext System B specification (also known as World System Teletext).

Five dedicated digital encoder registers, DEN_TTX1 to DEN_TTX4, and DEN_TTXM, program the teletext encoding in various areas of the vertical blanking interval (VBI) of each field. Four of these areas (that is, blocks of contiguous teletext lines) can independently be defined within the two VBIs of one frame (for example, two blocks in each VBI, or three blocks in *field1* VBI and one in *field2* VBI). In certain circumstances it is possible to define up to four areas in each VBI.

DENC supports the following most commonly used teletext standards for DVB applications:

- TTXT-B (WST-PAL): 45 bytes 2 bytes of clock run-in, 1 byte framing code, 42 bytes of data,
- TTXT-C (NABTS-NTSC): 39 bytes 2 bytes of clock run-in, 1 byte framing code, 36 bytes of data.

There are two teletext operating modes:

- VBI: Teletext data on selected 18 VBI lines (e.g. ITU-R lines 6 to 23 and 318 to 335),
- Full Page: Teletext data replace video data (includes ITU-R lines 24 to 311 and 336 to 623).

26.3 Teletext packet format

One TTXT-B teletext packet (otherwise called a teletext line) is a stream of 360 bits, transferred at an average frequency of 6.9375 MHz. The data format is the same as the contents of the PES data packet as defined in the ETSI specification.

Each teletext packet is composed of the clock run in and the data field, as illustrated in Figure 98.

- The clock run in is composed of two bytes, each with the hexadecimal value 0xAA (binary value 1010 1010).
- The data field consists of three fields, framing code, magazine and packet address, and data block fields.

These three fields provide the block of teletext data.

The framing code is a single byte of hexadecimal value 0xE4¹. The data is transmitted in order, from the LSB to the MSB of each byte in memory.

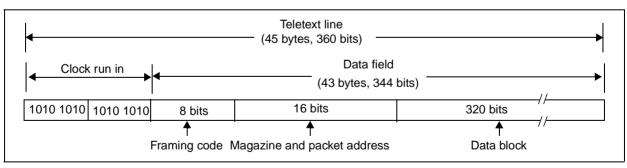

Figure 98: Teletext packet format

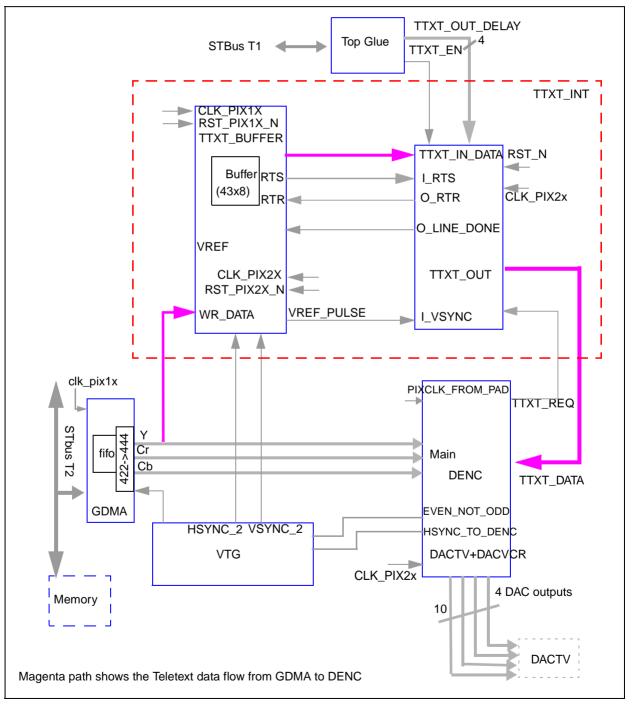

^{1.} Specification for conveying ITU-R Systems B teletext in digital video broadcasting (DVB) bit streams.

26.4 Data transfer sequence

As shown in Figure 99 the teletext interface block (TTXT_INT) contains a 43 bytes buffer (TTXT_BUFFER), which is filled with teletext data by the GDMA at 13.5 Mbytes per second. When requested by the DENC, the teletext serial encoder TTXT_OUT reads this data in bytes from the TTXT_BUFFER, serially encodes it and sends it to the DENC at 6.9375 Mbits per second.

In memory, one line of teletext data is stored as the framing code + data bytes, where data_bytes are defined by the teletext standard. The two bytes of clock run-in are provided by the TTXT_OUT block at the beginning of every teletext line.

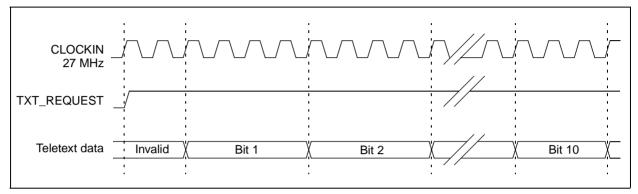

The digital encoder issues a teletext request signal to the teletext serial encoder, this is shown by the rising edge of signal TTXT_REQUEST in Figure 100. After a delay, programmable from two to nine master clock periods, the teletext serial encoder transmits the first valid teletext data bit of the teletext packet.

The 360 bits of output data are defined as nine 37-bit sequences, ending with one 27-bit sequence. Within each sequence, each bit is transmitted in four 27 MHz cycles, except bits 10, 19, 28 and 37, which are transmitted in three 27 MHz cycles. This is illustrated in Figure 100 for bits 0 to 10.

The duration of the TTXS window is 1402 reference clock periods (51.926 μ s), which corresponds to the duration of 360 teletext bits.

The delay between signal TTXT_REQUEST becoming high and the transfer of the first bit of the teletext packet is between two and nine, 27 MHz clock cycles. This delay is programmed by register bits TTXDEL[2:0] (DEN_TTX1). The value written to this register is increased by two 27 MHz clock cycles, so the value 0 corresponds to an overall delay of two x 27 MHz clock cycles, and the value seven corresponds to a delay of nine x 27 MHz clock cycles.

5 Interrupt control

VTG interrupts can be programmed to interrupt the CPU as follows:

- when the current video frame toggles odd to even or even to odd,
- every selected teletext data line per field.

The interrupt status is given by the VTG_ITS status register and masked by the VTG_ITM register. The interrupt bits are reset when the CPU writes to the register VTG_ITS.

27 TV out registers

Addresses are provided as the *TtxtBaseAddress* + offset.

The TtxtBaseAddress is:

0x2090 0700.

[0] TTXT_ENABLE

Enable TTXT_OUT block to digital encoder.

28 Graphics DMA (GDMA)

28.1 Overview

The graphics DMA (GDMA) moves graphics content from memory to the digital encoder. It supports the following list of features:

- link-list based display engine for multiple viewport capabilities,
- YCbCr4:2:2R, YCbCr888 input formats for display viewport,
- byte format for VBI viewport.

The GDMA fetches two premultiplied pixel data formats from the external memory in little endian format:

- YCrCb888 (601 only),
- YCbCr422 (601 only).

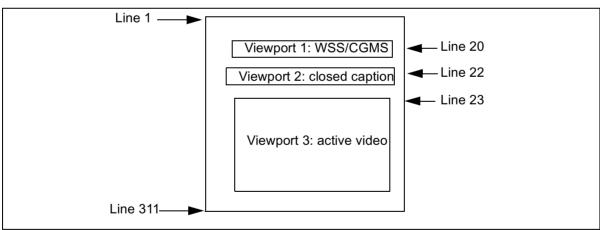

It delivers YCbCr888 to the digital encoder.

The GDMA supports four types of vertical data insertion:

- closed captioning (NTSC:21 and/or 284),(PAL:22 and/or 335),
- wide screen signalling WSS (NTSC:23),(PAL:20 and/or 283),
- copy generation management generation CGMS (NTSC:23),(PAL:20 and/or 283),
- teletext (NABTS/WST): Up to 43 bytes of data per teletext line from memory to TTXT_INT block inside TV out, which serially encodes it and passes it to the DENC

Four invisible viewports are used to insert data during vertical blanking time, plus one viewport for active video. See Figure 101.

Figure 101: PAL example for VDI data insertion by a graphical object from memory

28.2 Viewports

A viewport is a physical rectangular area defined in the screen area by four parameters which locate the top left and bottom right corner. The GDMA controls the multiple viewport display from a display instruction list (link list) stored in the external memory. It can provide VBI or output display content, which can be either in a single viewport or split into several viewports.

When several viewports are defined within a layer, only one viewport can be associated with any given video scan line. This means that there is always one line between two linked viewports. If VBI data is present on adjacent lines, one viewport two lines high should be used.

Where no viewport is defined for a screen location, GDMA output is automatically blanked (the color output is equal to the blanking color set in the GDMA_CTL register).

A pixmap stored in the external memory must be attached to each viewport. For the video nodes this pixmap is the output display composed by the blitter engine. This is defined by the registers GDMA_PML (pixmap memory location) and GDMA_PTY (pixmap memory type).

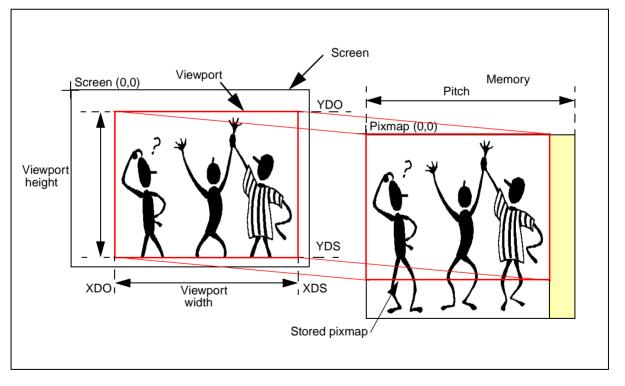

Each viewport has the following parameter list defined in GDMA_VPO and GDMA_VPS:

- XDO: horizontal start location of top left pixel,
- YDO: vertical start location of top left pixel,
- XDS: horizontal start location of bottom right pixel,
- YDS: vertical start location of bottom right pixel.

The vertical (YDO,YDS) co-ordinates are field-based.

28.3 Output pixmap display

Figure 102: Output display attached to a viewport, NTSC: 720 x 480, PAL: 720 x 576

Viewports are linked together by a link-list which describes the output display. Each viewport is attached to a bitmap stored in external memory. The link-list describing the output display is built in the external memory. This is constructed as a series of nodes linked by the node pointers GDMA_NVN or GDMA_NIN.

The link-list is field-based for an interlaced display. This means two nodes must be provided for each viewport, one node for the TOP field and another for the BOTTOM field.

There are two types of link-lists:

- VBI link-list,
- video link-list.

VBI data is output before the final video display data (see Figure 103). Each type of link-list uses a different pointer, GDMA_NVN for video data and GDMA_NIN for VBI data. The VBI node should not be vertically adjacent to the video node in memory. This is programmed in the GDMA_LVF register which provides the scan line number for the first video data node to be fetched.

GDMA_LVF is interpreted according to the field or frame configuration. The interlaced environment is field based.

Each pixmap node has the following parameter list:

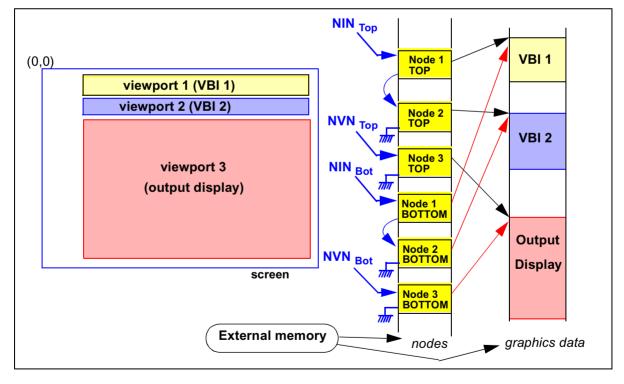

- pixmap color format,
- pixmap pitch,
- linear start address (pixel accurate).

Width and height are computed from the XDO, XDS, YDO and YDS values. Width = XDS - XDO + 1 and height = YDS - YDO + 1.

The linear start address is the address for retrieving the pixmap pixel displayed in the upper-left corner of the viewport, that is the address of the window (0,0) pixel.

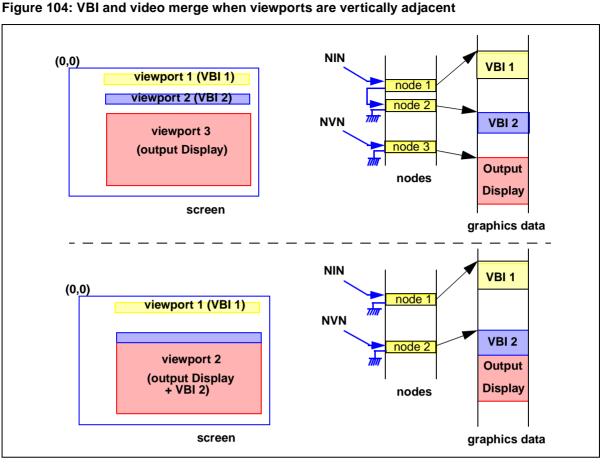

The YDO and YDS values are specified in reference to frame line numbering, even in an interlaced display.

Figure 103: Typical display link-list configuration for interlaced display

Note: Software must leave at least one blank line between two different viewport types. Before switching from a VBI to a video node, the GDMA must load the video node, and then enough video data to fill the pipe. This means that if a VBI node and the video viewport need to be vertically adjacent in memory, the software must increase the video viewport height to include the VBI viewport.

57

In interlaced displays VPO and VPS line number values vary depending on the TOP or BOTTOM field, so that each viewport can be vertically positioned with one line accuracy. See Figure 105.

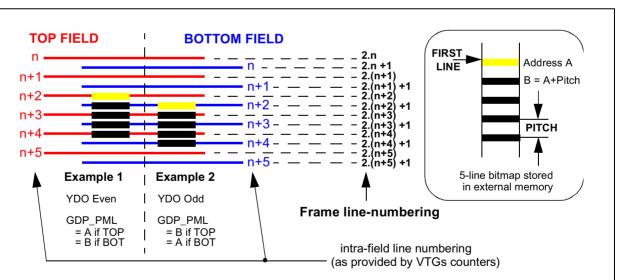

Figure 105: Line numbering convention in an interlaced display

1 - During the TOP FIELD, the VTG counter must be compared to (YDO+1 >> 1) & (YDS >> 1) for detecting the viewport active area.

2 - During the BOTTOM FIELD, the VTG counter must be compared to (YDO >> 1) & (YDS-1 >> 1) for detecting the viewport active area.

3 - Whatever the field, TOP OR BOTTOM, the first bitmap line to read from memory is always at the memory location specified by the GDP_PML register. It is the responsibility of the software to program this register according to the field parity.

ل ۲۸

28.3.1 Starting the display

VBI (VDI) link list

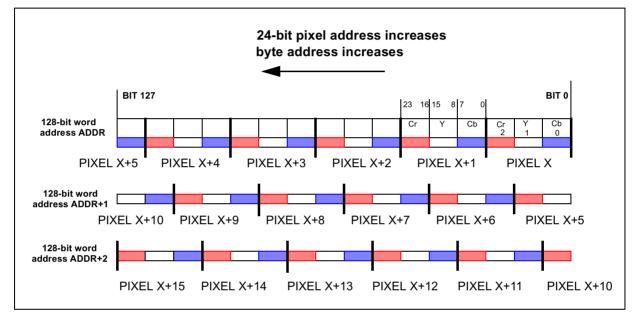

If VBI_PRESENT in GDMA_CTL is set, the GDMA fetches the associated node. Once the line counter reaches the associated line number it then starts fetching the data.

Video link list

To start the display of these nodes, two registers are set. GDMA_NVN points to the first video node, and GDMA_LVF gives the line number to reach before starting to load this node.

28.3.2 Input format

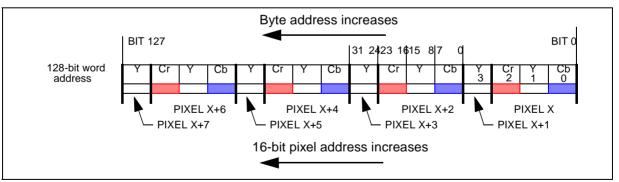

Confidentia

Note: 1 The memory address for pixel [0:0] must be aligned on a 32-bit word address boundary.

2 The pitch value must be a multiple of four bytes.

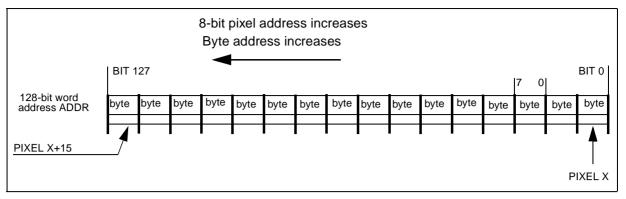

Figure 107: YCbCr 4:2:2 (16 bpp)

Note: 1 The memory address for pixel [0:0] must be aligned on a 32-bit word address boundary.

- 2 The pitch value must be a multiple of four bytes.
- 3 X is even in Figure 107.

Figure 108: Byte alignment in a 128-bit word

Note: The memory address for pixel [0:0] must be byte-aligned.

29 Graphics DMA (GDMA) registers

All the registers are memory mapped. The block occupies a 64 x 32-bit word address range. Addresses are provided as the *GDMABaseAddress* + offset.

The GDMABaseAddress is:

0x2090 0C00

30 Digital encoder (DENC)

The DENC supports PAL/NTSC/SECAM encoding. It gives RGB, CVBS and Y/C outputs.10-bit video DACs are integrated on the device. DENC supports Macrovision 6.1/7.01 copy protection which can be enabled by an anti-fuse. It also supports teletext re-insertion in vertical blanking interval. The VCR output is the same as the TV output.

The digital encoder (DENC) is a high performance PAL/SECAM/NTSC digital encoder. It converts one 4:4:4 digital video stream into a standard analog baseband PAL/SECAM/NTSC signal and into RGB and YPrPb analog components.

The DENC can handle interlaced mode in all standards. It can perform closed-captions, CGMS, WSS, VPS and teletext encoding and allows Macrovision[™] 7.01/6.1 copy protection. Four analog output pins are available.

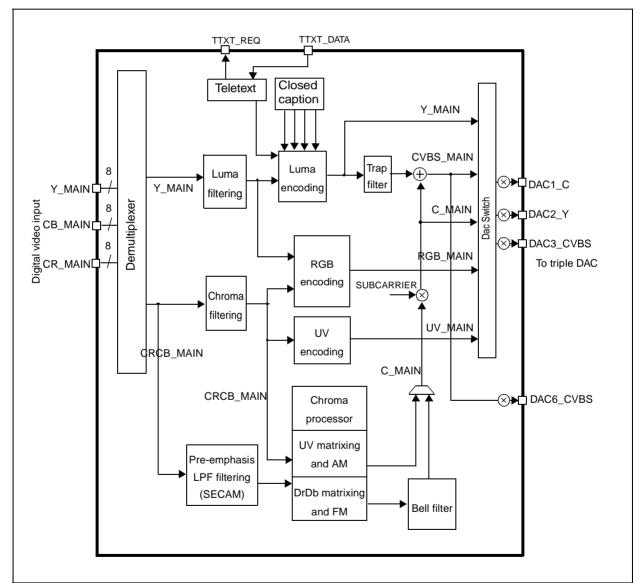

Figure 109: STx5119 digital encoder block diagram

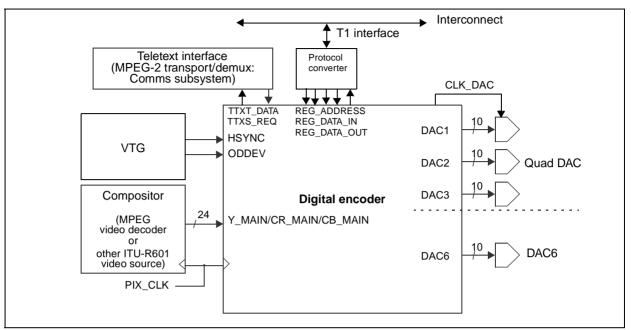

30.1 Main features

- NTSC-M, PAL-BDGHI, N, M, SECAM plus NTSC-4.43 encoding (optional pedestal in PAL and NTSC standards).
- Four simultaneous analog outputs on four 10-bit DACs: S-VHS (Y_MAIN/C_MAIN) + CVBS_MAIN + CVBS_MAIN or RGB_MAIN + CVBS_MAIN or Pr_MAIN + Y_MAIN+ Pb_MAIN + CVBS_MAIN
- Macrovision[™] Rev7.01/Rev6.1 copy protection process in NTSC, PAL and SECAM.
- Cross-color reduction by specific trap filtering on luma within CVBS flow for the CVBS output.
- Closed-captioning, CGMS, WSS, VPS encoding and teletext encoding with included sequencer and shaping for CVBS_MAIN coming independently from main video input.
- Digital frame sync input/ODDEV, programmable polarity and relative position.
- Digital horizontal sync input/output (HSYNC), programmable polarity and relative position.
- Full or partial vertical blanking.
- Luma filtering with 2x oversampling and sin y / y correction.
- Chrominance filtering with 4x oversampling to either 1.1 MHz, 1.3 MHz, 1.6 MHz or 1.9 MHz (in PAL and NTSC) and chrominance filtering according to relevant SECAM standards.
- Both luma and chrominance filtering are with programmable coefficients on main video path.
- Wide chrominance bandwidth for RGB encoding (2.45 MHz if CRCB are input at 6.75 MHz and 5.8 MHz if CRCB are input at 13.5 MHz rate).
- Saturation, contrast and brightness control of 4:4:4 main.
- 24-bit direct digital frequency synthesizer for color subcarrier.
- Programmable reset of color subcarrier phase (4 modes).
- Programmable access via parallel port.
- Programmable (4 bits) output levels RGB (-20% to +17%), C versus Y in CVBS and S-VHS (0 to +23.5%), PrPb (-25% to +22%), Y and CVBS (-25% to +22%) and C (-25% to +22%).
- 4:4:4 input can be encoded on both RGB (YPrPb) and CVBS (S-VHS) outputs (programmable).
- Autotest operation mode (on-chip color bar pattern 100/0/75/0).

30.2 Brief overview

Figure 110: Typical DENC application

The DENC can operate either in master mode, where it supplies all sync signals, or in six slave modes, where it locks onto incoming sync signals. The main functions are controlled from a microcontroller via a parallel port.

Data input format

The digital input is through three separate 8-bit buses carrying Y, Cb and Cr at 13.5 MHz. Input samples are latched in on the rising edge of the clock signal PIX_CLK. Figure 110 illustrates the expected data input format. The video input of 24 bits (Y_MAIN/CB_MAIN/CR_MAIN) must be synchronous. The encoding of the main 4:4:4 input is enabled by programming DAC123_CONF as RGB or YPrPb or Y/C/CVBS analog outputs.

Standard	Application	PIX_CLK (MHz)	Pixel rate (MHz)	Field rate (Hz)	Vertical resolution
PAL-B, D, G, H, I PAL-N, SECAM	ITU-R601	27	13.5	50	625
NTSC-M, PAL-M	ITU-R601	27	13.5	60	525

Table 82: Subcarrier frequencies in	ITU-R601 mode
-------------------------------------	---------------

The input pixel data has an integer relationship to the number of clock cycles per horizontal line as detailed in Table 83.

Standard	Application	Pixel clock (MHz)	Total pixels per line	Active pixels per line
PAL-B, D, G, H, I PAL-N, SECAM	ITU-R601	13.5	864	720
NTSC-M, PAL-M	ITU-R601	13.5	858	720

30.4 Video timing

The DENC outputs interlaced video in PAL-BDGHI, PAL-N, PAL-M or NTSC-M standards (NTSC- 4.43 is also possible) and SECAM.

The burst sequences are internally generated, subcarrier generation being performed numerically with PIX_CLK as reference. 4-frame bursts are generated for PAL or 2-frame bursts for NTSC. Rise and fall times of synchronization tips and burst envelope are internally controlled according to the relevant ITU-R and SMPTE recommendations. The 6-frame subcarrier phase sequence is generated in SECAM (see Section 30.11 on page 308).

Figure 114 to Figure 119 depict typical VBI waveforms.

Incoming YCrCb data may be encoded on those lines of the VBI that do not bear line sync pulses or pre/post-equalization pulses. This mode of operation is referred to as partial blanking and is the default set-up. Any VBI data present in digitized form in the incoming YCrCb stream (such as supplementary closed-captions line or StarSight ® data) may be kept in the encoded waveform in this way. Alternatively, the complete VBI may be fully blanked, so no incoming YCrCb data is encoded on these lines.

Complete VBI comprises the following lines:

- for 525/60 systems (SMPTE line numbering convention): lines 1 to 19 and second half of line 263 to line 282,
- for 625/50 systems (CCIR line numbering convention): second half of line 623 to line 22 and lines 311 to 335.

Partial VBI consists of:

- for 525/60 systems (SMPTE line numbering convention): lines 1 to 9 and second half of line 263 to line 272,
- for 625/50 systems (CCIR line numbering convention): second half of line 623 to line 5 and lines 311 to 318.

Full or partial blanking is controlled by configuration bit BLKLI (DEN_CFG1).

Note: 1 Line 282 in 525/60/SMPTE systems is either fully blanked or fully active.

2 Line 23 in 625/60/CCIR systems is always fully active.

In an ITU-R656-compliant digital TV line, the active portion of the digital line is the portion included between the SAV (start of active video) and EAV (end of active video) words. However, this digital active line starts somewhat earlier and may end slightly later than the active line usually defined by analog standards.

The DENC allows two approaches:

STMicroelectronics Confidential

• Encodes the full digital line (720 pixels / 1440 clock cycles). In this case, the output waveform reflects the full YCrCb stream included between SAV and EAV.

296/543

• Drops some YCrCb samples at the extremities of the digital line so that the encoded analog line fits within the analog ITU-R/SMPTE specifications.

Selection between these two modes of operation is performed with bit ALINE (DEN_CFG4).

In all cases, the transitions between horizontal blanking and active video are shaped to avoid too steep edges within the active video. Figure 119 on page 300 gives timings concerning the horizontal blanking interval and the active video interval.

Note: The burst envelope shown here indicates the location from which the first subcarrier positive zero crossing is sought (with respect to the 0_H reference). The normal burst always starts with such a positive zero crossing.

30.5 Master Mode

In this mode, the DENC supplies HSYNC and ODDEV sync signals (with independently programmable polarities) to drive other blocks. Refer to Figure 120 and Figure 121 for timings and waveforms. The DENC starts encoding and counting clock cycles as soon as the master mode has been loaded into the control register (Reg.0). Configuration bits "Syncout_ad[1:0]" (Reg4) allow to shift the relative position of the sync signals by up to 3 clock cycles to cope with any YCrCb phasing.

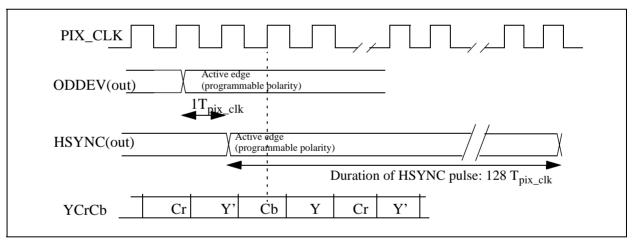

Figure 120: ODDEVEN, VSYNC and HSYNC waveforms

Note: When ODDEV is a sync input, only one edge ("the active edge") of the incoming ODDEV is taken into account for synchronization. The "non-active" edge (2nd edge on this drawing) is not critical and its position may differ by $\pm H/2$ from the location shown.

The HSYNC pulse width indicated is valid when the DENC supplies HSYNC. In those slave modes where it receives HSYNC, only the edge defined as active is relevant, and the width of the HSYNC pulse it receives is not critical.

Figure 121: Master mode sync signals

30.6 Slave modes

30.6.1 Introduction

A number of slave modes are available: ODDEV+HSYNC based (line-based sync), VSYNC+HSYNC based (another type of line-based sync), ODDEV-only based (frame-based sync), VSYNC-only based (another type of frame-based sync), or sync-in-data based (line locked or frame locked).

ODDEV refers to an odd/even (also known as not-top/bottom) field flag, HSYNC is a line sync signal, VSYNC is a vertical sync signal. Their waveforms are shown in Figure 120. The polarities of HSYNC and VSYNC/ODDEV are independently programmable in all slave modes.

30.6.2 Line-based synchronization

HSYNC + ODDEV based synchronization

Synchronization is performed on a line-by-line basis by locking onto incoming ODDEV and HSYNC signals (refer to Figure 122 for waveforms and timings). The polarities of the active edges of HSYNC and ODDEV are programmable and independent.

 PIX_CLK INPUT IN

Figure 122: HSYNC + ODDEVEN based slave mode sync signals

The first active edge of ODDEV initializes the internal line counter, but encoding of the first line does not start until an HSYNC active edge is detected (at the earliest, an HSYNC transition at the same time as ODDEV). At this point, the internal sample counter is initialized and encoding of the first line starts. Then encoding of each subsequent line is individually triggered by HSYNC active edges. The phase relationship between HSYNC and the incoming YCrCb data is normally such that the first clock rising edge following the HSYNC active edge samples Cb (that is, a blue chroma sample within the YCrCb stream). It is, however, possible to internally delay the incoming sync signals (HSYNC + ODDEV) by up to 3 clock cycles to deal with different data and sync phases, using configuration bits SYNCIN_AD[1:0] (DEN_CFG4).

The DENC is thus fully slaved to the HSYNC signal, which means that lines may contain more or less samples than usual.

- If the digital line is shorter than its nominal value the sample counter and all internal synchronization signals are re-initialized when the early HSYNC arrives.
- If the digital line is longer than its nominal value the sample counter is stopped when it reaches its nominal end-of-line value and waits for the late HSYNC before re-initializing.

The field counter is incremented on each ODDEV transition. The line counter is reset on the HSYNC following each active edge of ODDEV.

HSYNC+VSYNC Based Synchronization

Synchronization is performed on a line-by-line basis by locking onto incoming VSYNC and HSYNC signals. Refer to Figure 123 for waveforms and timings. The polarities of HSYNC and VSYNC are programmable and independent.

The incoming VSYNC signal is immediately transformed into a waveform identical to the odd/ even waveform of an ODDEV signal, therefore the behavior of the core is identical to that described above for ODDEV+HSYNC based synchronization. Again, the phase relationship between HSYNC and the incoming YCrCb data is normally such that the first clock rising edge following the HSYNC active edge samples "Cb" (i.e. a 'blue' chroma sample within the YCrCb stream). It is however possible to internally delay the incoming sync signals (HSYNC+VSYNC) by up to 3 clock cycles to cope with different data/sync phases, using configuration bits SYNCIN_AD

The field counter is incremented on each active edge of VSYNC.

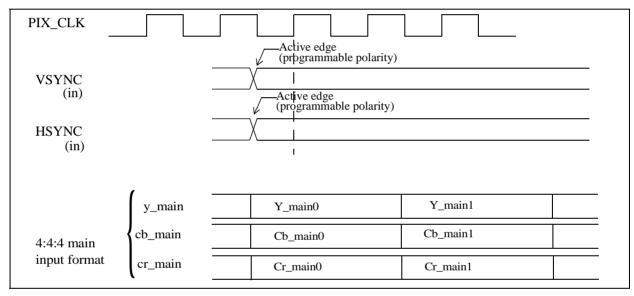

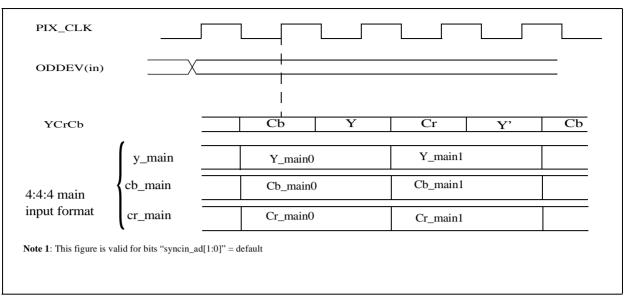

Figure 123: HSYNC + VSYNC Based Slave Mode Sync Signals

Note: This figure is valid for bits "syncin_ad[1:0]" = default

The active edges of HSYNC and VSYNC should normally be simultaneous. It is permissible that HSYNC transitions before VSYNC, but VSYNC must nottransition before HSYNC.

Figure 124: ODDEVEN Based Slave Mode Sync Signals

Note: This figure is valid for bits "syncin_ad[1:0]" = default

30.7 Autotest mode

An autotest mode is available, which causes the DENC to produce a color bar pattern in the appropriate standard, independently of the video input.

The autotest mode is started by setting field SYNC[2:0] to 111 (DEN_CFG0). As this mode sets the DENC in master mode, VSYNC/ODDEV and HSYNC signals are in output mode. Table 85 shows the decimal values of Y, Cr and Cb corresponding to the autotest color bar. This mode should not be used for quality measurements and is for DENC and DACs testing only.

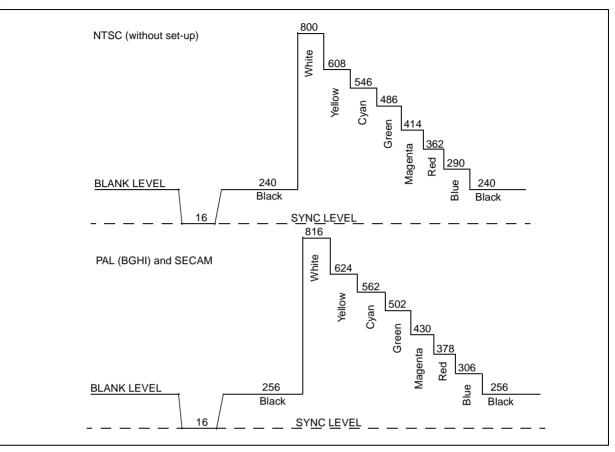

Color	Y	Cr	Cb
Black	16	128	128
Blue	36	116	212
Red	64	212	100
Magenta	84	200	184
Green	112	56	72
Cyan	136	44	156
Yellow	160	140	44
White	236	128	128

Table 85: Autotest color bar Y, Cr, Cb decimal values

The corresponding decimal output values just before the DACs are shown graphically in Figure 125. The figure shows the static values corresponding to the input values in Table 85.

Input demultiplexor

The incoming YCrCb data, as well as Y4 and CrCb in 4:4:4 mode, is demultiplexed into a blue-difference chroma information stream, a red-difference chroma information stream and a luma information stream. Incoming data bits are treated as blue, red or luma samples according to their relative position with respect to the sync signals in use and configuration bits SYNCIN AD (DEN CFG4). Brightness, saturation and contrast are then performed on demultiplexed data (refer to registers DEN_BRIGHT to DEN_SATUR).

The ITU-R601 recommendation defines the black luma level as Y = 16 and the maximum white luma level as Y = 235. Similarly it defines 225 quantification levels for the color difference components (Cr, Cb), centered around 128. Accordingly, incoming YCrCb samples can be saturated in the input multiplexer with the following rules (after saturation, brightness and contrast stage):

 for Cr or Cb samples: 	Cr,Cb > 240 => Cr,Cb saturated at 240
	Cr,Cb < 16 => Cr,Cb saturated at 16
 for Y samples: 	Y > 235 => Y saturated at 235
	Y < 16 => Y saturated at 16

This avoids having to heavily saturate the composite video codes before digital-to-analog conversion if erroneous or unrealistic YCrCb samples are input to the encoder (there may

Confidential 8.05

otherwise be overflow errors in the codes driving the DACs). This avoids generating a distorted output waveform.

However, in some applications, it may be desirable to let extreme YCrCb codes pass through the demultiplexer. This is controlled using bit MAXDYN (DEN_CFG6). In this case, only codes 0x00 and 0xFF are overridden: if such codes are found in the active video samples, they are forced to 0x01 and 0xFE.

In any case, the YCrCb codes are not overridden for EAV/SAV decoder.

30.9 Subcarrier generation

A direct digital frequency synthesizer (DDFS) generates the required color subcarrier frequency using a 24-bit phase accumulator. This oscillator feeds a quadrature modulator which modulates the baseband chrominance components.

The subcarrier frequency is obtained from the following equation:

Fsc = (24-bit increment word / 2²⁴) x PIX_CLK

Hardwired increment word values are available for each standard and can be automatically selected. Alternatively in PAL and NTSC (according to bit SELRST in DEN_CFG2), the frequency can be fully customized by programming other values into a dedicated increment word register (DEN_IDFSn). This allows NTSC-4.43 or PAL-M-4.43 to be encoded, for instance.

The following procedure is used.

- 1. Program the required increment in registers DEN_IDFSn.
- 2. Set bit SELRST_INC to 1 in register DEN_CFG5.
- Perform a software reset (DEN_CFG6). Caution: this sets all bits from DEN_STA onwards to their default value. Alternatively, set register DEN_CFG8 bits PH_RST_MODE to 01, in which case the frequency (and phase) is updated on the beginning of next video line.

lote: if a standard change occurs after software reset, the increment value is automatically reinitialized with the hardwired or loaded value according to bit SELRST_INC.

The reset phase of the color subcarrier can also be software-controlled by registers DEN_PDFSn.

The subcarrier phase can be periodically reset to its nominal value to compensate for any drift introduced by the finite accuracy of the calculations. In PAL and NTSC, subcarrier phase adjustment can be performed every line, every eighth field, every fourth field, or every second field (VALRST in DEN_CFG2). If SECAM is performed, subcarrier phase is reset every line.

30.10 Burst insertion (PAL and NTSC)

The color reference burst is inserted so it always starts with a positive zero crossing of the subcarrier sine wave (except in some cases where Macrovision anti-copy is active). The first and last half-cycles have a reduced amplitude so that the burst envelope starts and ends smoothly.

The burst contains 9 or 10 sine cycles of 4.43361875 MHZ or 3.579545 MHz (depending on the standard programmed in register DEN_CFG0), as follows:

9 cycles of	3.579545 MHz
10 cycles of	4.43361875 MHz
9 cycles of	3.579545 MHz
9 cycles of	3.579545 MHz
	10 cycles of 9 cycles of

The burst can be turned off (no burst insertion) by setting BURSTEN to 0 (DEN_CFG2).

Two strategies exist for burst insertion: one merely gates and shapes the subcarrier for burst insertion, the other is more elaborate and always starts the burst with a positive-going zero crossing. In the first case, the phase of the subcarrier when the burst starts is not controlled, with the consequence that some of its first and last cycles are more heavily distorted. The second solution guarantees smooth start and end of burst with a maximum of undistorted burst cycles, and can only be beneficial to chroma decoders. It is the solution implemented in the DENC.

While the first option gave constant burst start time but uncontrolled initial burst phase, the second solution guarantees start on a positive-going zero crossing with the consequence that two burst start locations are visible over successive lines, according to the line parity. This is normal and explained below.

In NTSC, the relation between subcarrier frequency and line length creates a 180° subcarrier phase difference (with respect to the horizontal sync) from one line to the next according to the line parity. So if the burst always starts with the same phase (positive-going zero crossing), this means the burst is inserted at time X or at time $X + T_{NTSC}/2$ after the horizontal sync tip according to the line parity, where T_{NTSC} is the duration of one cycle of the NTSC burst.

With PAL, a similar rationale holds, and again two burst start locations are possible. The subcarrier phase difference (with respect to horizontal sync) from one line to the next in this case is either 0 or 180° with the following series: A-A-B-B-A-A-..., where A denotes A-type bursts and B denotes B-type bursts, A-type and B-type being 180° out of phase with respect to horizontal sync. So 2 locations are possible, one for A-type, the other for B-type (see Figure 115).

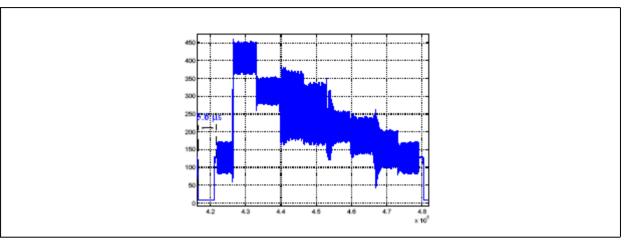

This assumes a periodic reset of the subcarrier is automatically performed (see VALRST[1:0] in DEN_CFG2). Otherwise, over several frames, the start of burst drifts within an interval of half a subcarrier cycle. This is normal and means the burst is correctly locked to the colors encoded. The equivalent effect with a gated burst approach would be the following: the start location would be fixed but the phase with which the burst starts (with respect to the horizontal sync) would drift.

30.11 Subcarrier insertion (SECAM)

Subcarrier frequency in SECAM mode depends on Cr and Cb values (frequency modulation). The color subcarrier frequency is 4 250 000 Hz for Cb = 128 (on blue lines) and 4 406 249 Hz for Cr = 128 on red lines. Frequency clipping values are 3 900 000 Hz and 4 756 250 Hz.

The insertion point of the non-modulated subcarrier is shown on Figure 126.

In odd fields the phase of subcarrier follows the sequence: 0, 0, π , 0, 0, π , 0, 0, π , ... compared to a sine wave starting at the same point - 5.6 µs after a horizontal sync pulse (inverted on one line out of every three and also at each frame). This sequence begins from line 1 or line 23 of the first field (see bit PHI_12_SECAM in DEN_CFG7). Bit INV_PHI_SECAM allows the inversion of this sequence (π , π , 0, π , π , 0,... instead of 0, 0, π , 0, 0, π ,...), in odd fields.

In even fields, the subcarrier sequence is always inverted compared to the odd field sequence.

To enable SECAM mode, a soft reset or loading of DEN_CFG0 (which is not taken into account) must be performed after setting SECAM to 1 in DEN_CFG7.

30.12 Luminance encoding

The demultiplexed Y samples are band-limited and interpolated at PIX_CLK clock rate. The resulting luminance signal is correctly scaled before insertion of any closed-captions, CGMS, VPS, WSS or teletext data, Macrovision copy-protection signals and synchronization pulses.

The interpolation filter compensates for the sin(x)/x attenuation inherent to digital/analog conversion and greatly simplifies the output stage filter (refer to Figure 127 to Figure 129 for characteristic curves with a 27 MHz reference clock).

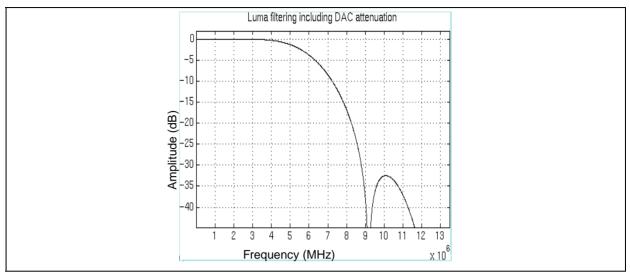

In addition, the luminance that is added to the chrominance to create the composite CVBS signal can be trap-filtered at 3.58 MHz (NTSC) or 4.43 MHz (PAL). This supports applications intended for low-end TV sets which are subject to cross-color if the digital source has a wide luminance bandwidth. The trap filter does not affect the S-VHS luminance output nor the RGB outputs.

Note: If SECAM is performed, a trap filter with 4.43 MHz cut-off frequency should always be enabled on the luma part of the CVBS signal (see bits MAIN_ENTRAP and TRAP_4.43 in DEN_CFG3).

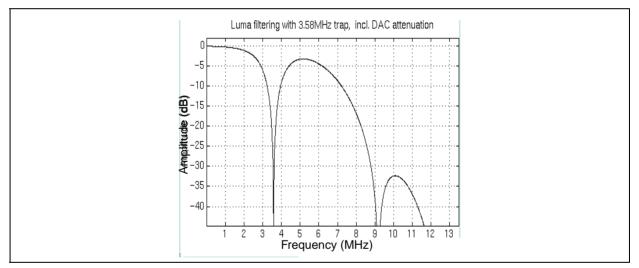

A 7.5 IRE pedestal can be programmed if needed with all standards (see DEN_CFG0 and DEN_CFG7). This allows in particular encoding of Argentinian and non-Argentinian PAL-N, or Japanese NTSC (NTSC with no set-up).

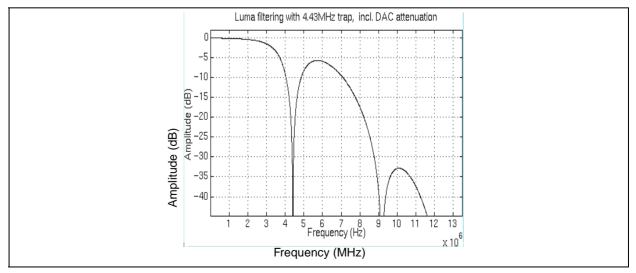

Ĺ**Ţ**

A programmable delay can be inserted on the luminance path to offset any chroma/luma delay introduced by off-chip filtering (chroma and luma transitions being coincident at the DAC output with default delay, see DEN_CFG3 and DEN_CFG4). The luma processing as well as line and field timings in SECAM mode are identical to PAL BDGHI ones.

30.13 Chrominance encoding

U, V (PAL and NTSC) and Dr, Db (SECAM) chroma components are computed from demultiplexed Cb, Cr samples. Before modulating the subcarrier, these are band-limited and interpolated at PIX_CLK clock rate. This processing eases the filtering following D/A conversion and allows more accurate encoding. A set of four different filters is available in PAL and NTSC for chroma filtering to fit a wide variety of applications in the different standards, and these include filters recommended by ITU-R 624-4 and SMPTE170-M. The preprogrammed 3-dB bandwidths are 1.1, 1.3, 1.6 or 1.9 MHz, and Figure 134, Figure 135 and Figure 136 show the various frequency responses with a 27 MHz reference clock (see DEN_CFG1 for programming).

The narrower bandwidths are useful against cross-luminance artefacts, the wider bandwidths keep higher chroma contents.

The DENC allows the use of software values for filter coefficients. This can be useful when other clock frequencies are used (24.545454 and 29.5 MHz clocks in square pixel mode) or for specific applications where another frequency response is needed. The chroma filter is 17 taps with symmetric coefficients and operates at PIX_CLK frequency (27 MHz default).

The upsampling (13.5 to 27 MHz with 27 MHz PIX_CLK) is performed by padding with zeros.

In SECAM, 1.3 MHz low-pass and pre-emphasis filtering are performed on Dr and Db chroma components, before the frequency modulation, according to ITU-R Rec624-4. Bell filtering is performed at the end of frequency modulation stage. Peak-to-peak amplitude of the modulated chrominance signal at the central frequency (4 279.7 kHz) is 22,88% of the black-white interval (22.88 IRE). Refer to Figure 131 for frequency response of bell filter with subcarrier frequencies and clipping values.

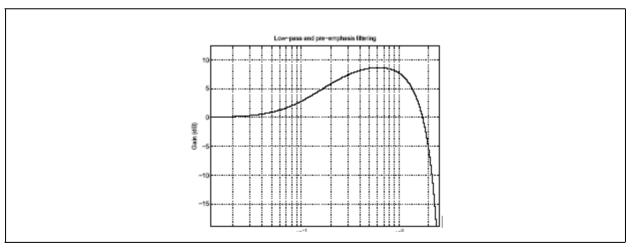

Figure 130: SECAM chrom	a filtering (pre-emphasis and 1	.3 MHz low pass filtering)
-------------------------	---------------------------------	----------------------------

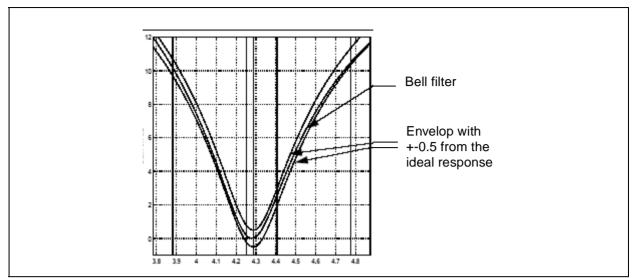

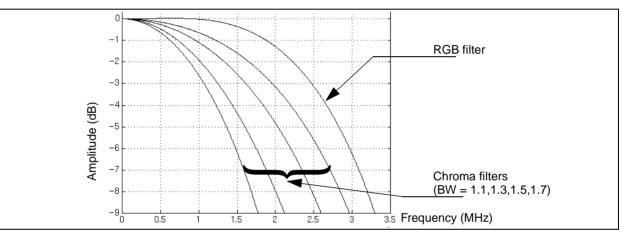

Figure 131: SECAM high frequency subcarrier pre-emphasis (bell filtering), including DAC attenuation

30.14 Composite video signal generation

The composite video signal is created by adding the luminance after trap filtering (optional in PAL and NTSC, see DEN_CFG3) and the chrominance components. A saturation function is included in the adder to avoid overflow errors should extreme luminance levels be modulated with highly saturated colors (this does not occur with natural colors, but may be generated by computers or graphic engines).

A color killing function is available, whereby the composite signal contains no chrominance, that is, replicates the trap-filtered luminance.

Note: This function does not suppress the chrominance on the S/VHS outputs (nevertheless suppressing the S-VHS chrominance is possible using bit BKDACn in DEN_CFG5, if chrominance signal is output on DAC n).

In some US applications, CVBS output is IF modulated before the antenna TV set input. Some IF modulators generate delay on the chroma part of the signal. This delay can be compensated in the DENC by adding delay on the luma part of the video signal before generating the composite (CVBS) signal.

Figure 133: 1.1 MHz chroma filter

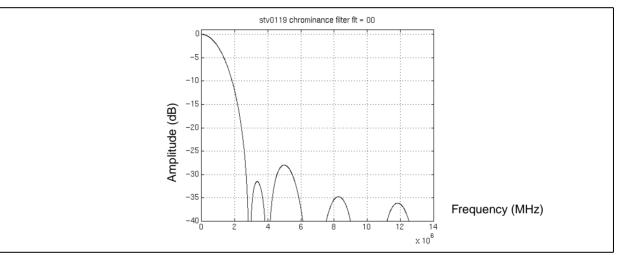

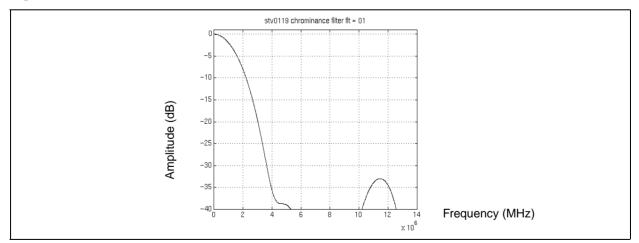

Figure 134: 1.3 MHz chroma filter

7939391A

Figure 135: 1.6 MHz chroma filter

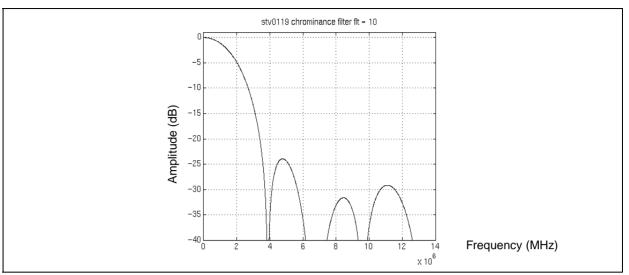

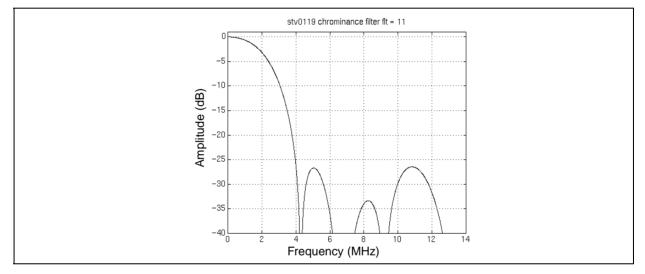

Figure 136: 1.9 MHz chroma filter

30.15 RGB and YPrPb (YUV) encoding

The Cr and Cb samples feed an x 2 interpolation filter. The resulting baseband chroma signal has a 2.45 MHz bandwidth (Figure 132) and is combined with the filtered luma component to generate R,G,B or U,V samples at PIX_CLK frequency rate. These filters are also programmable if the need arises.

Identical filtering to luma filtering (see Figure 127) is performed on all components (YCRCB_MAIN). In this case, DAC 2 output data is encoded from Y_MAIN input if YPRPB_MAIN (YUV_MAIN) configuration is used (see bits DAC123_CONF in DEN_CFG13).

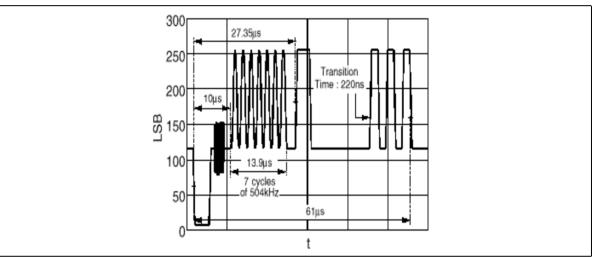

30.16 Closed-captioning

Closed-captions (or data from an extended data service as defined by the closed-captions specification) can be encoded by the DENC. The closed-caption data is delivered to the circuit through the register interface. Two dedicated pairs of bytes (two bytes per field), each pair preceded by a clock run-in and a start bit, can be encoded and inserted on the luminance path on a selected TV line. The clock run-in and start code are generated by the DENC.

Closed-caption data registers are double-buffered so that loading can be performed anytime, even during line 21/284 or any other selected line.

User register DEN_CCCF11 (or DEN_CCCF21) contains the first byte to send (LSB first) after the start bit on the appropriate TV line in field 1 (or field 2), and DEN_CCCF12 (DEN_CCCF22) contains the second byte to send. The TV line number where data is to be encoded is programmable (DEN_CCLIF1, DEN_CCLIF2). Lines that may be selected include those used by the StarSight data broadcast system. Closed-caption data has less priority than CGMS but more priority than Macrovision anticopy signals programmed for the same line.

The internal clock run-in generator is based on a direct digital frequency synthesizer. The nominal instantaneous data rate is 503.496 kHz (that is, 32 times the NTSC line rate). Data low corresponds nominally to 0 IRE, data high corresponds to 50 IRE at the DAC outputs (see Figure 137).

When closed-captioning is on (bits CC1/CC2 in DEN_CFG1), the CPU should load the relevant registers (DEN_CCCF11 and 2, or DEN_CCCF21 and 2) once every frame at most (although there is some margin due to the double-buffering). Bits BUF2_FREE and BUF1_FREE are set in DEN_STA if the closed-caption data registers are loaded too frequently. These can be used to regulate loading rate.

The closed-caption encoder considers that closed-caption data has been loaded and is valid on completion of the write operation into register DEN_CCCF12 for field 1, into DEN_CCCF22 for field 2. If closed-caption encoding has been enabled and no new data bytes have been written into the closed-caption data registers when the closed-caption window starts on the appropriate TV line, the circuit outputs two US-ASCII null characters with odd parity after the start bit.

30.17 CGMS encoding

CGMS (copy generation management system, also known as VBID and described by standard CPX-1204 of EIAJ) data can be encoded by the circuit. Three bytes (20 significant bits) are delivered to the chip via the register interface. Two reference bits (1 then 0) are encoded first, followed by 20 bits of CGMS data (including a cyclic redundancy check sequence, not computed

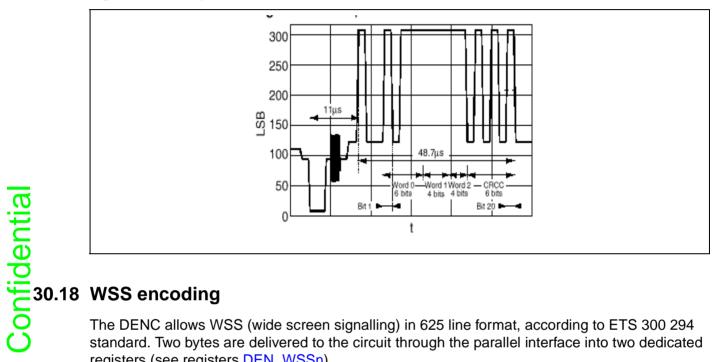

by the device and supplied to it as part of the 20 data bits). The reference bits are generated locally by the DENC. Refer to Figure 138 for a typical CGMS waveform.

When CGMS encoding is enabled, the CGMS (see bit ENCGMS in DEN CFG3) waveform is present once in each field, on lines 20 and 283 (SMPTE-525 line numbering). CGMS data has priority over any Macrovision anticopy signals programmed for the same line.

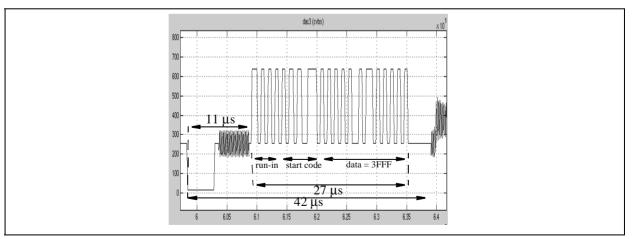

The CGMS data register is double-buffered, which means that it can be loaded anytime (even during line 20/283) without any risk of corrupting CGMS data that could be in the process of being encoded. The CGMS encoder considers that new CGMS data has been loaded and is valid on completion of the write operation into register DEN_CGMS3. CGMS always has priority over any Macrovision anticopy signals programmed for the same line.

Figure 138: Example of CGMS waveform

The DENC allows WSS (wide screen signalling) in 625 line format, according to ETS 300 294 standard. Two bytes are delivered to the circuit through the parallel interface into two dedicated registers (see registers DEN_WSSn).

Figure 139: Example of WSS waveform

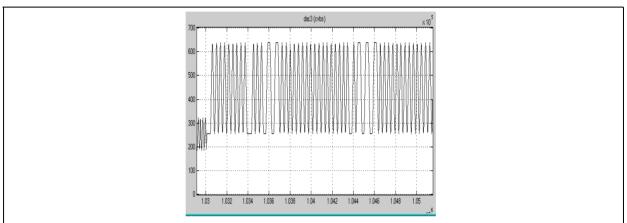

When WSS encoding is enabled (see bit ENWSS in DEN_CFG3), the waveform is present on the first half of line 23, on each frame. Refer to Figure 139 for an example of WSS waveform. Data is preceded by a run-in sequence and a start code generated locally by the DENC. Different WSS data for same line are not supported. The same WSS waveform is simultaneously present for the two CVBS outputs.

30.19 VPS encoding

VPS data (as defined by ETS 300 231 communication from June 1993) can be encoded by the DENC on line 16 (CCIR) for 625 line PAL and SECAM television systems. VPS data is delivered to the circuit through the parallel interface (see registers DEN DACC to DEN BRIGHT). Data transmission is preceded by a clock run-in and a start code generated by the DENC. The clock frequency is 5 MHz. This feature is enabled by setting ENVPS (DEN CFG7). Figure 140 shows an example of a VPS waveform.

The DENC can encode teletext according to the CCIR/ITU-R Broadcast Teletext System B specification, also known as World System Teletext and NABTS (North American Basic Teletext

30.20 Teletext encoding The DENC can encode t *specification*, also known Specification - EIA-516). In DVB applications, telet transport layer CPU (or c store teletext packets in a performed by the GDMA In DVB applications, teletext data is embedded within DVB streams as MPEG data packets. The transport layer CPU (or demultiplexer) must sort out incoming data packets and, in particular, store teletext packets in a buffer, which then passes them to the DENC on request. This is performed by the GDMA + TTXT INT block inside the TVO block.

30.20.1 Signals exchanged

The DENC and the TTXT INT block exchange two signals: TTXS (teletext sync) from the DENC to the TTXT INT block and TTXD (teletext data) from the TTXT INT block to the DENC.

TTXS is a request signal generated on selected lines. In response to this signal, the TTXT_INT block sends teletext bits to the DENC for insertion of a teletext line into the analog video signal (360 in case of teletext B - WST in PAL or 288 in case of teletext C - NABTS in NTSC).

The teletext system is selected by register DEN_TTXCFG bits TTXT_ABCD[1:0].

The duration of TTXS corresponds to the number of bits to be transmitted for the teletext standard selected (288, 296, 320 or 360 bits) with the protocol described below. In teletext B and 625 line systems (WST), the duration of the TTXS window is 1402 reference clock periods, which corresponds to the duration of 360 teletext bits (see Section 30.20.2).

• [9 x (33 x 4 PIX_CLK + 4 x 3 PIX_CLK) + (25 x 4 PIX_CLK + 2 x 3 PIX_CLK)]

In teletext C and 525 line systems (NABTS), this duration is 1121 master clock periods.

[7 x (33 x 4 PIX_CLK + 4 x 3 PIX_CLK) + (26 x 4 PIX_CLK + 3 x 3 PIX_CLK)]

Following the TTXS rising edge, the encoder expects data from the TTXT INT block after a programmable number (2 to 9) of master clock periods (PIX CLK). Data is transmitted synchronously with the master clock at an average rate of 6.9375 Mbit/s (27 MHz reference clock) according to the protocol described below. It consists, in transmission order, of 16 clock

run-in bits, 8 framing code bits and n that represents one teletext packet (336 bits, 42 bytes, in teletext B - 625 lines and 288 bits, 36 bytes, in teletext C -525 line systems). If more than n bits are transmitted (n depends on the standard selected), they are ignored by the DENC. Two bits change in framing code from one teletext standard to another, so the DENC can blank them and put the right bits instead, according to the standard selected (see DEN_TTXCFG and DEN_DACC). This can be useful if the teletext interface can deliver only the framing code for teletext B-625 line standard (WST).

30.20.2 Transmission protocol

So as to transmit the teletext data bits at an average rate of 6.9375 Mbit/s, which is about 1/3.89 times the master clock frequency (case of 27 MHz master clock), the following scheme is adopted.

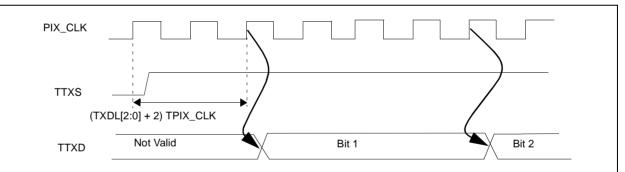

The 360-bit packet is regarded as nine 37-bit sequences plus one 27-bit sequence. In every sequence, each teletext data bit is transmitted as a succession of four identical samples at 27 Msample/s, except for the 10th, 19th, 28th and 37th bits of the sequence which are transmitted as a succession of three identical samples.

30.20.3 Programming

• TTXS rising to first valid sample delay programming

The encoder expects the teletext buffer to clock out the first teletext data sample on the $(2 + N)^{\text{th}}$ rising edge of the master clock following the rising edge of TTXS (Figure 141 depicts this graphically for N = 0). N is programmable from 0 to 7 (that is, overall delay is programmable from two to nine PIX_CLK cycles) via 3 dedicated bits located in register DEN_TTXn: TTXDEL[2:0].

Figure 141: TTXT rising to first-valid-sample delay for TTXDEL[2:0] = 0

Teletext line selection

Five dedicated registers (from registers DEN_TTXn for CVBS_main) allow to program teletext encoding on various lines of the vertical blanking interval (VBI) of each field. Each line in VBI can be selected independently. Refer to registers DEN_TTXn for details. Moreover, full page teletext encoding is possible using bit FP_TTXT from DEN_TTX1. In this case, teletext is encoded on lines 24 to 311 and 336 to 623 (ITU-R line numbering), in addition to lines already programmed by registers DEN_TTXn. When full page teletext is performed, no video data is encoded (Y_MAIN input stream is ignored). Different teletext data for both the composite videos is not supported.

• Amplitude of encoding

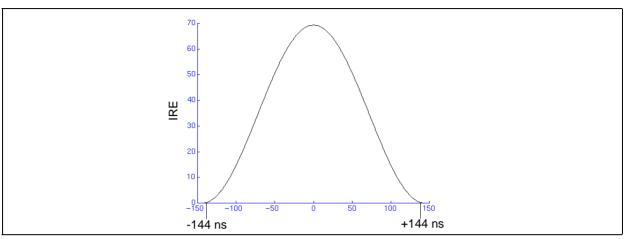

In 525 lines systems the default teletext amplitude is 70 IRE. If TTXT100IRE is set (DEN_DACC), the teletext amplitude is 100 IRE.

Confidential

• Teletext pulse shape

The shape and amplitude of a single pulse are depicted in Figure 142, its relative power spectral density is given in Figure 143 and is basically zero at frequencies above 5 MHz, as required by the World System Teletext specification.

30.21 Macrovision copy protection process rev7.01/6.1

The chrominance, luminance and composite video signals on CVBS_MAIN and R, G, B video signals can be altered according to the Macrovision[™] copy protection process, Revision 7.01. and Revision 6.1.

A programming document is available to those customers who have executed a license or a nondisclosure agreement with Macrovision Corporation.

30.22 CVBS, S-VHS(Y/C), RGB and UV outputs

The STx5119 provides signals to the main output. These signals are designated as follows:

- CVBS: CVBS_MAIN
- S-VHS: Y_MAIN/C_MAIN
- RGB: RGB_MAIN
- UV: UV_MAIN

Video signals can be directed to three analog output pins through 10-bit DACs operating at the reference clock frequency. The available combinations are described by bits DAC123_CONF of DEN_CFG13.

Note: DAC6 is always hardwired to CVBS_MAIN and hence not programmable.

The C to Y peak-to-peak amplitude ratio can be modified in both CVBS and VHS (Y/C) outputs (see DEN_CMULT and TTXS, Register 65 bits c_mult[3:0]).

The default peak-to-peak amplitude of UV and RGB outputs is set to 70% of Y or CVBS peak-topeak amplitude, for 100/0/100/0 color bar pattern. It is possible to use the maximum DAC dynamic when RGB is being output by changing RGB_MAXDYN to1 of DEN_CFG13 when DAC123_CONF is 010.

U and V outputs have 0.7 V peak-to-peak amplitude if 100/0/100/0 color bar pattern is input. In all cases, UV outputs can be multiplied by 0.75 to 1.22 factor according to DEN_DAC13 and DEN_DAC34 bits DAC1_MULT[5:0] and DAC1_MULT[5:0] respectively.

A single external analog power supply pair is used for all DACs, but two independent pairs of current and voltage references are needed. Each current reference pin normally connects externally to a resistor tied to the analog ground, whilst each voltage reference pin normally connects to a capacitance tied to the analog ground.

The internal current sources are independent from the positive supply, and the consumption of the DACs is constant whatever the codes converted.

Any unused DAC may be independently disabled by software, in which case its output is at neutral level (blanking for luma and composite outputs, no color for chroma output, black for RGB and UV outputs). For applications where a single CVBS output is required, the RGB/CVBS and S-VHS/UV DAC should be disabled and pins VIDANAREXT[1:0] tied to the analog power supply.

Due to the 3.3 V power supply used, the output swing of the DACs is about 1 Vp-p. Therefore some external gain may be required, which, combined with the recommended output filtering stage, means active filtering. For this active filtering stage to be very simple, it is possible to invert the DAC outputs by programming a user register bit (DEN_CFG5). Code N becomes code 1024 - N, that is, the resulting waveform undergoes a symmetry around the mid-swing code.

31 Digital encoder (DENC) registers

Note: Do not change the value of reserved bits from their default values. Addresses are provided as the DENCBaseAddress + offset. The DENCBaseAddress is: 0x2090 0000.

Reset:	Undefined						
Description:	When SEC	CAM (<mark>DEN_C</mark>	FG8) = 0 (PA	L and NTS	C)		
7	6	5	4	3	2	1	0
		Rese	rved			O23	O22

In any of the following conditions when SELRST = 0 (DEN_CFG5), the phase accumulator is initialized with the ten MSBs of this register:

3

017

2

O16

1

O15

• after a 0-to-1 transition of bit RSTOSC (DEN_CFG2),

4

018

• after a standard change,

5

019

• when cyclic phase readjustment has been programmed (DEN_CFG2.VALRST[1:0]).

The 14 remaining LSBs loaded into the accumulator in these cases are all zeroes (defining the phase reset value with a 0.35° accuracy).

If SELRST = 0 (for example after a hardware reset) the phase offset used every time the DDFS is re initialized is a hardwired value. The hardwired values cannot be read out of the DENC. These are:

- 0xD9 C000 for PAL BDGHI, N, M,
- 0x1F C000 for NTSC-M,
- 0x00 0000 (blue lines),
- 0x43 C000 (red lines) for SECAM.

To use these registers instead of the hardwired values follow the procedure below.

- Load the registers with the required value.
- Set SELRST to 1 (DEN_CFG2).
- Perform a software reset (DEN_CFG6), or set RSTOSC_BUF to 1 (DEN_CFG6, this puts the soft phase value into a tampon register) and set PH_RST_MODE[1:0] (DEN_CFG8) to put this value into an accumulator at the beginning of the next line.

These registers are never reset and must be explicitly written to.

Description:	When SECAM (DEN_0	CFG8) = 1 (two SECAM subcarriers)
--------------	-------------------	-----------------------------------

7	6	5	4	3	2	1	0
B21	B20	B19	B18	B17	B16	B15	B14
7	6	5	4	3	2	1	0
R21	R20	R19	R18	R17	R16	R15	R14

When bit SELRST = 1, this register configures the static phase offset for digital frequency synthesizer for two SECAM subcarriers (8 MSB only) (blue lines - DEN_PDFS1 and red lines - DEN_PDFS2).

These registers contain the 8 bits (21 to 14) of the value with which the phase accumulator of the DDFS is initialized on every line in SECAM mode. The phase is calculated with 1.4° accuracy as:

- DEN_PDFS1 x 16384 (decimal), or DEN_PDFS1 x 0x4000 (blue lines)
- (256 + DEN_PDFS1 + DEN_PDFS2) x 16384 (decimal), or (100 + DEN_PDFS1 + DEN_PDFS2) x 0x4000 (red lines)

If bit SELRST = 0 (for example after a hardware reset) the phase offset used every time the DDFS is re initialized is a hard wired value. The hard wired values cannot be read out of the DENC. These are:

- 0xD9 C000 for PAL BDGHI, N, M,
- 0x1F C000 for NTSC-M,
- 0x00 0000 (blue lines),
- 0x43 C000 (red lines) for SECAM.

To validate use of these registers instead of the hard wired values, follow the PAL and NTSC mode.

The registers are never reset and must be explicitly written to.

TTXDEL[2:0]: teletext data latency. The encoder clocks the first teletext data sample on the (2 + TXDL[2:0])th rising edge of the master clock, following the rising edge of TTXS (teletext synchronization signal, supplied by the encoder). Default value: 100

TTX_L*n*: Each of these bits enables teletext on line X (ITU-R line numbering and 625 line systems). For teletext line selections for other standards, refer to Table 87 below. Default value: 0

1. Default mode when pin NOT_RESET is active (low level).

Type: Read/write

Buffer: Immediate

Reset: See table below

Description: These registers contain the nine coefficients and three control bits for the chroma filter, which are described in the table below. Values from these registers are used only when MAIN_FLT_S is set to 1. This bit has highest priority over the rest. When MAIN_FLT_S is set to 0 the default values of the coefficients are loaded depending on the mode selected or the type of filter selected in a particular mode with FLT (DEN_CFG1). If SECAM square pixel mode is performed, the values from these registers are loaded and their default values correspond to that standard.

The coefficients are chosen to give the required filter response for a specific application according to the symmetrical FIR filter equation:

 $H(z) = C_0 + C_1 z^{-1} + C_2 z^{-2} + ... + C_7 z^{-7} + C_8 z^{-8} + C_7 z^{-9} + ... + C_2 z^{-14} + C_1 z^{-15} + C_0 z^{-16}$ The register reset values give the coefficients for the SECAM square pixel mode. Each register value is calculated by adding an offset value to the desired coefficient value, according to the relationship: *register value* = *offset* + *actual coefficient value*. For instance, to obtain a *coefficient value* of 5 for C4, which has an offset of 32, the register DEN_CFCOEF4 must contain the value 100101, which is the binary equivalent of 32 + 5. The offset values for each coefficient are listed in the table below. Filter sampling frequency is PIX_CLK (27 MHz, 24.545454 MHz or 29.5 MHz).

MAIN_PLG_DIV[1:0]: this value is chosen depending on what the sum of all the coefficients is.00: when sum of coefficients = 51201: when sum of coefficients = 1024 (default)10: when sum of coefficients = 204811: when sum of coefficients = 4096

Type: Read/write

Buffer: Immediate

Reset: See table below

Description: These registers contain the ten coefficients for the luma filter, which are described in the table below. Values from this register is used only when FLT_YS (DEN_CDEL_LFC) is set to 0. The coefficients give the required filter response for a specific application according to the symmetrical RIF filter equation:

 $H(z) = A_0 + A_1z^{-1} + A_2z^{-2} + ... + A_8z^{-8} + A_9z^{-9} + A_8z^{-10} + ... + A_2z^{-16} + A_1z^{-17} + A_0z^{-18}$ The values of the coefficients LU_COEF0 through to LU_COEF7 must be entered in two's complement form and the remainder as normal positive values. Sampling frequency of the filter is PIX_CLK (27 MHz, 24.545454 MHz or 29.5 MHz). The control bits for this filter are in register DEN_CDEL_LFC.

Coefficient	Reset value	Reset setting
LU_COEF0[4:0]: coefficient number 0	0 0001	A0 = +1
LU_COEF1[5:0]: coefficient number 1	11 1111	A1 = -1
LU_COEF2[6:0]: coefficient number 2	111 0111	A2 = -9
LU_COEF3[6:0]: coefficient number 3	000 0011	A3 = +3
LU_COEF4[7:0]: coefficient number 4	0001 1111	A4 = +31
LU_COEF5[7:0]: coefficient number 5	1111 1011	A5 = -5
LU_COEF6[8:0]: coefficient number 6	1 1010 1100	A6 = -84
LU_COEF7[8:0]: coefficient number 7	0 0000 0111	A7 = +7
LU_COEF8[8:0]: coefficient number 8	1 0011 1101	A8 = +317
LU_COEF9[9:0]: coefficient number 9	01 1111 1000	A9 = +504

Working frequency of this filter is the one of PIX_CLK (27, 24.545454 or 29.5 MHz), and the filtering is done on upsampled signal (half PIX_CLK to PIX_CLK frequency by padding by zeros).

32 Video timing generator (VTG)

The video timing generator (VTG) provides video synchronization signals internally to sub-blocks of the TV out module (GDMA and digital encoder) as well as externally to the blitter and host CPU.

The video timing generator in STx5119 is master. As master It automatically generates synchronization signals and associated counter values. The VTG delivers HSYNC (horizontal synchronization signal) and VSYNC (vertical synchronization signal) starting from hard or soft reset and calibrated by register information such as the number of samples per line and the number of half lines in a field).

Note: The VTG works in interlaced mode only.

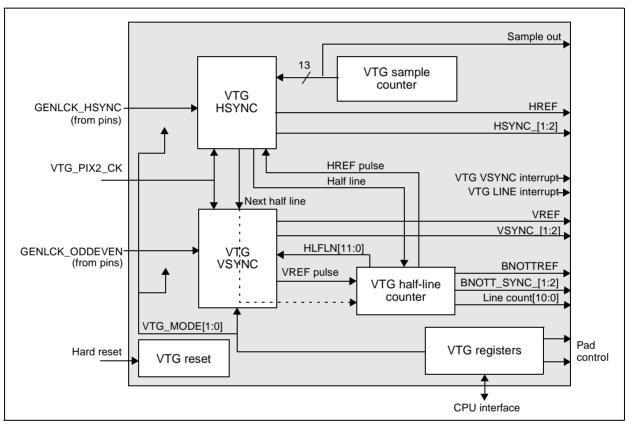

Figure 145: Block diagram

32.1 Signal generation

Horizontal and vertical synchronization signals are either fixed or programmable.

32.1.1 Fixed signals

There are three fixed signals, HREF, VREF and BNOTTREF.

- HREF is high during 64 samples and the rising edge occurs when the pixel counter takes the value 0.
- VREF is high during 64 samples and the rising edge occurs when the line counter takes the value 1 in progressive mode or on the top field, in interlaced mode on the bottom field. VREF occurs when the line count takes the value 0.
- BNOTTREF toggles each rising edge of VREF.

32.1.2 Programmable signals

The rising and falling edges of these signals are fully programmable and refer to line count and sample count (see registers VTG_H_HD_n, VTG_TOP_V_VD_n, VTG_BOT_V_VD_n, VTG_TOP_V_HD_n and VTG_TOP_V_HD_n). Vertical delay must match the line counter (for interlaced mode, the first line of the top field is line 1 but the first line of the bottom field is line 0). Horizontal delay must match the sample counter (for interlaced mode on bottom field line 0, VTG_BOT_V_VD_n delay must be CLKLN / 2 to take into account the field changes at the middle of the horizontal excursion).

The sample granularity for horizontal delays allows the edge of the sync to be phased on the rising or falling edge of the pixel clock.

32.1.3 Other signals

The BNOTT_SYNC_n signal toggles each rising edge of VSYNC.

The video timing generator generates two interrupts, one on every VSYNC and the other on a programmed line number.

32.2 Master mode

See Figure 146: Master mode waveforms on page 354.

The parity of the half line number (VTG_HLFLN register) determines the position of VREF regarding the HREF position. After a reset, VREF and HREF are activated at the same time to generate a top field (VTG_BNOTT_REF = 0). The half line counter is cleared and the line counter is set to one (VREF and HREF are detected in phase). The vertical count is incremented each time the horizontal count reaches the end of line value (VTG_CLKLN register). HREF is then produced and a pulse activated, every half line increments a half line counter. When this counter is equal to HLFLN - 1, VREF is activated. If HALF_LINE_NUMBER is odd a VREF occurs but HREF is not present. The vertical and half line counters are cleared and a bottom field is generated (VTG_BNOTT_REF = 1).

Next time the half line counter reaches HALF_LINE_NUMBER - 1, both VREF and HREF are generated and a top field is generated. If VREF is activated in phase with or without HREF, the video timing generator works in interlaced mode.

If HALF_LINE_NUMBER is even, VREF is always generated in phase with HREF and the video timing generator works in progressive mode. Each time a VREF occurs the signal BNOTTREF toggles.

From VREF, HREF and BNOTTREF two sets of synchronization signals are generated:

- set 1: HSYNC_1, VSYNC_1, BNOTT_SYNC_1,
- set 2: HSYNC_2, VSYNC_2, BNOTT_SYNC_2.

Programmable register values allow the adjustment of the rising and falling edges of the HSYNC_n and VSYNC_n signals. The BNOTT_SYNC_n signals toggle each rising edge of the associated VSYNC_n signal.

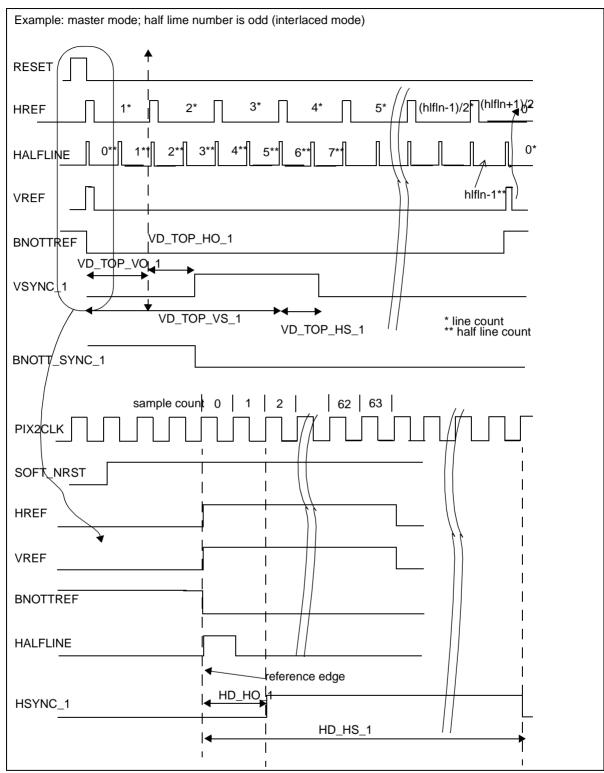

In the waveform in Figure 146 only set 1 is drawn. The values of VD_TOP_VO_1, VD_TOP_HO_1, VD_TOP_VS_1 are duplicated for the bottom field. HD_HO_1 and HD_HS_1 are available for the top and bottom field.

These values are duplicated for set 2 with the suffix _2.

Note: A VTG_DISABLE bit is implemented in the VTG_MOD register. This signal disables line and sample counters. After reset this signal is activated and the video timing generator does not run before the bit is reset.

	VTG_DRST
Address:	VTG BaseAddress + 0x48
Туре:	Write
Reset:	0
Description:	Writing to this register resets the sample counter and line counter of the video timing generator. The reset is activated once on writing at this address. None of the existing register configurations are lost on writing to this register. It can be used in any mode (master/slave), and could be invoked, for example, if the module is not working although the configuration is correct. When activated, this reset activates VREF and HREF. If the video timing generator is in interlaced mode (that is half lines per vertical number is odd) a top field is generated. In slave mode, after soft reset the output syncs (VREF, HREF) go to their in-active states (as programmed in VTG_MOD register). The module then waits for the programmed active edge of input syncs (HSYNC_IN, VSYNC_IN or ODDEVEN_IN) and when it occurs, it synchronizes on to it and re-generates the synchros with active edges as programmed in VTG_MOD register

Description:	This register contains a set of bits which represents the status of the video timing generator. Any change from 0 to 1 of any of these bits sets the corresponding bit of the VTG_ITS register, and can thus potentially cause an interrupt on VTG_IRQ_1 or VTG_IRQ_2. VST, VSB, LNT and LNB are pulses and are unlikely ever to be read as a 1.
[31:8]	Reserved

- [7] **LNT**: line number top set for a short time when line counter reaches LINE_NUMBER_TOP value in register VTG_LN_INTERRUPT in the top field.
- [6] **LNB**: line number bot set for a short time when line counter reaches LINE_NUMBER_BOT value in register VTG_LN_INTERRUPT in the bottom field.

[5] Reserved

- [4] **VST**: VSYNC top set for a short time at the beginning of the top field, corresponding to the falling edge of the internal BNOTT signal.
- [3] **VSB**: VSYNC bottom set for a short time at the beginning of the bottom field, corresponding to the rising edge of the internal BNOTT signal.

34 Quadruple video DAC

34.1 Overview

The STx5119 has one quadruple, 10-bit, video DAC that provides output signals in CVBS+RGB, CVBS+YUV or SVHS(Y/C) + CVBS + SCVBS. Figure 147 shows the DAC architecture.

A reference circuit controlled by one external precision resistor sets the full-scale output for the quadruple DAC. The voltage across the resistor is defined by an internal bandgap reference circuit. Dedicated pads are used to ensure good noise immunity.

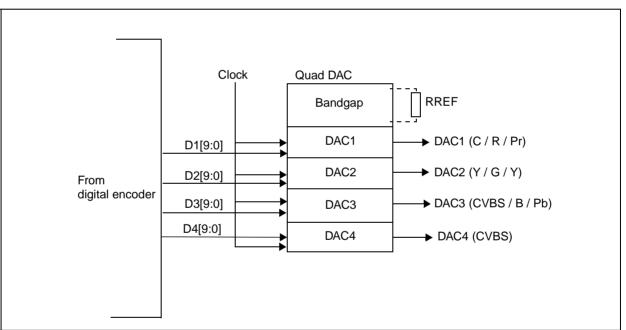

The quadruple DAC uses a 6/4 segmented architecture. The four least significant bits control a binary weighted current matrix and the six most significant bits control a thermometric current matrix. It is able to output 8 mA current.

The generic DAC current sources may provide an output range of up to 1.6 V with good linearity. Sampled data is available on video outputs after one clock period on the next rising clock edge.

Dedicated 3.3 V analog and digital power and ground supplies are used to reduce noise effects. The main digital 1.2 V supply uses the chip core VDD and GND.

The DAC output settings are controlled by DEN_CFG13.

Figure 147: Quadruple video DAC schematic

34.2 Input codes for video application

The table below lists the reference input codes generated by the digital encoder depending on the configuration for the DACs and the standard.

Table 89: Reference input codes

	Y-PAL/SECAM	Y-NTSC	RGB
WHITE(235)	816.00	800.00	616.00
BLACK(16)	256.00	240.00	41.00
SYNC TIP	16.00	16.00	-

Note: CVBS = Y + C, therefore chrominance component has no effect on the CVBS signal (C is null).

34.3 Video output voltage level

The resistor R_{ref} connected to the bandgap, controls the DAC output current. For the maximum code (1023 in decimal):

l_{out} (max) = 77.696 / R_{ref}

For example, with a typical value of $R_{ref} = 9.7 \text{ k}\Omega$, I_{out} (max) = 8 mA for each DAC.

The value of R_{ref} must be greater or equal to 9.7 k Ω so as not to exceed the maximum output current. Due to the sensitive relationship between the DAC and R_{ref}, the tolerance of R_{ref} value must be small, typically 1%.

The output voltage on the RGB output pins depends on the external load resistor R_{load} (connected between the DAC output and ground):

 V_{out} (max) = $R_{load} * I_{out}$ (max)

For example, with a typical load value

 R_{load} = 165 Ω, I_{out} (max) = 8 mA, V_{out} (max) = 1.32 V.

Vout should always be lower than 1.6 V to guarantee linearity.

For any given digital input code, the output voltage of the DAC is given by the following formula:

 $V_{out} = D_{in} / 1023 * V_{out} (max) = (D_{in} * R_{load} * 77.696) / (R_{ref} * 1023)$

 $V_{out} = D_{in} * R_{load} * 0.0759 / R_{ref}$

For example, with $R_{load} = 165 \Omega$, $R_{ref} = 9.7 k\Omega$ and $D_{in} = 802$, $V_{out} = 1.04 V$.

34.4 Video specifications and DAC set up

In Y-PAL/SECAM, the output video range between code 16 (synchronization level) and code 816 (white level) should be: V_{out} (816) - V_{out} (16) = 1 V. The output video range between code 256 (black level) and code 816 (white level) should be 700 mV. This must be respected for all applications.

The value of the R_{ref} resistor must be chosen according to the value of R_{load} and the previous formula, to achieve the standard output video range. The minimum value for R_{ref} is 9.7 k Ω .

According to video specifications ITU-R BT 601, the nominal sampling frequency is 27 MHz. The DACs clock is buffered from the digital encoder clock, which is usually generated externally by a DCO. It must be as clean as possible to achieve a good signal to noise ratio.

The video DAC is enabled and managed through bits 9 to 16 in the Interconnect Config register D as shown in Table 90 and Table 91.

HZ	POFF	Power state
0	0	Normal Mode
1	0	High Impedance
Х	1	Power off Mode

Table 91: Video DAC command management

Х	1	0	Imax	0	
Х	1	1	lmax / 2	lmax / 2	

Confidential 34.5

4.5 Output stage adaptation and amplification

Figure 148 shows the block diagram of the output stage. The purpose of the output stage depends on the application and the required price to performance ratio. The output stage is connected directly to a SCART connector or to other components (in which case the output signal level and impedance may be different).

The amplifier gain must be in accordance with one of the Quad-DACs (defined by R_{load} and R_{ref}). If the amplifier gain cannot be set to the standard output video range by R_{ref} and R_{load}, it can be tuned. In common applications (with R_{ref} = 9.7 k Ω and R_{load} = 165 Ω), a video amplifier with a +6 dB gain should be adequate. The ideal input impedance of the output stage should be greater than R_{load}.

The Quad-DACs have no cut off frequency, therefore, a low pass filter (around 10 MHz) must be applied to remove harmonics of (mainly) 27 MHz. If additional attenuation is applied by the filter due to imperfection in the amplifier (generally degrading the C/L ratio), correction must be applied to preserve performance. Also, to guarantee good frequency behavior at high frequency, the analog power supply must be separate from the digital power supply. If this is not the case, additional correction may be required.

Audio decoder 35

35.1 Overview

The audio decoder subsystem consists of a dedicated core and a hardware wrapper that interfaces the core to the PCM player and S/PDIF player through the STBus interconnect. The audio decoder receives the elementary stream (ES) data. PTS extraction, start code detection and the routing of un-decoded Dolby® Digital streams to the S/PDIF is managed by software.

The PCM player is described in Chapter 37: PCM player on page 380 and S/PDIF player is described in Chapter 39: S/PDIF player on page 388.

35.1.1 Input formats

The audio decoder accepts:

- MPEG-1 layers I and II,
- MPEG-2.

35.1.2 Audio video synchronization

Skip frame, pause blocks and soft mute frame features are used to synchronize audio and video data, these features are implemented by software. Soft muting of the audio DACs is achieved by setting bit 18 in the CONFIG_CONTROL_D register.

Setting Settin

Sampling frequencies of $F_e = 48, 44.1, 32 \text{ kHz}$ and half sampling frequencies are supported.

5.1.4 Audio decode data flow

The audio subsystem architecture is shown in Figure 149, and the decode flow is shown in figure

The decode flow is described below.

- 1. Following demultiplexing, the PTI stores PES data in a buffer located in external memory.
- 2. The host CPU software reads the PES bit-buffer, performs PES parsing and detects the sync words for MPEG1-layers I and II. The PTS extracted from the PES header is stored together with the associated sync words addresses in the SyncWord and PTS buffer in external memory.
- 3. The host CPU software parses the ES data and uses it to verify correct sync word detection. Bit rate and sampling frequency information included in the ES stream can be extracted by the CPU or read from the audio decoder. The audio frame boundaries can be determined and the frame size checked.
- 4. The audio decoder, which also has an internal sync detector, is fed with ES data starting at the sync word boundary. The decoder latency is approximately 7000 cycles for layer 1 and 9500 cycles for layer 2. Only one frame is present inside the decoder at any instant. The sync word is not 32-bit aligned, software ensures that no false synchronization pattern is present before the correct sync word. The ES data is decoded and the PCM data is fed to the decoder output. The decoder signals when PCM decoded data is available. On detection of a CRC error, the CRC detector generates an interrupt (if enabled). If a CRC error occurs, frame decoding continues (the correct number of samples is produced but with corrupted values) and a flag is raised. Soft-mute is performed by software and not by the decoder core. Soft muting of the audio DACs is achieved by setting bit 18 in the CONFIG_CONTROL_D register.

- 5. The FDMA uses pacing signals from the decoder to write the compressed data and to read the decoded PCM data.
- 6. The audio/video synchronization is performed by the sync detector software in the CPU. The software controls the FDMA to skip one or more frames when the decoded data is written to the PCM player.
- 7. In compressed mode, the data is extracted directly from the circular buffer and formatted according to the IEC-61937 standard.
- 8. It is also possible to output the decoded PCM data on the S/PDIF interface according to the IEC-60958 standard. Data formatting is managed by the CPU software.

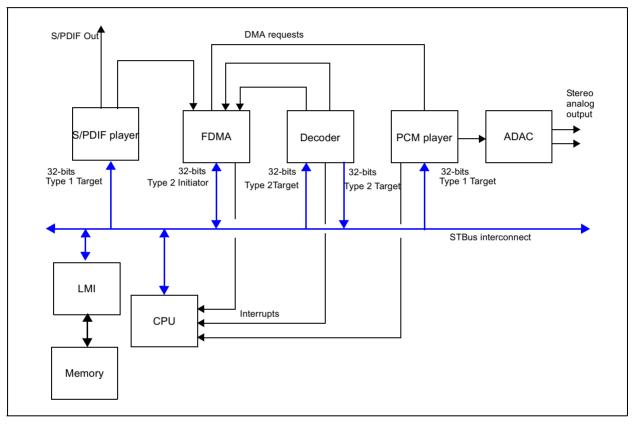

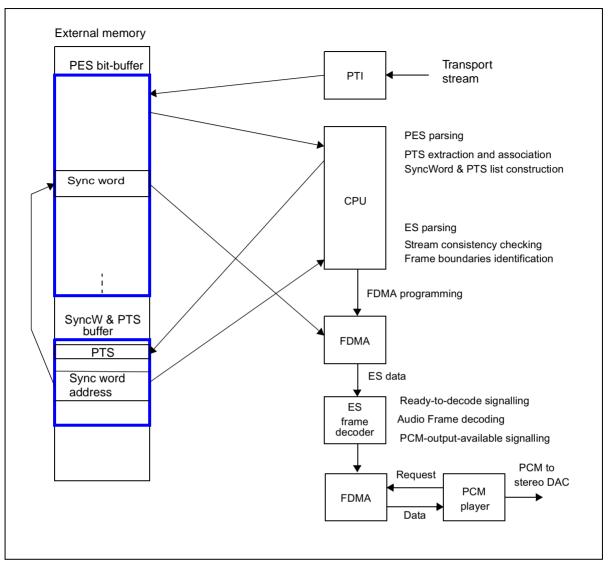

Figure 149: Audio system architecture

Figure 150: Audio decode flow

35.1.5 Reset

Software resets the audio decoder using the following procedure.

- 1. Soft reset: 1 is written to register AUD_DEC_CONFIG. The decoder remains in the reset state as along as the soft reset bit is asserted. The decoder comes out of the reset only after the soft reset bit is reset to 0 by the software.
- 2. Asserting the soft-reset doesn't change the contents of any other register. Other registers are modified separately by writing to them.
- 3. An interrupt is asserted, if enabled, after the decoder core is soft reset.
- 4. The soft reset bit in AUD_DEC_STATUS register signals the completion of a soft reset.

The decoder core is ready to decode frames after a hardware or soft reset.

35.1.6 Clocks

The audio decoder uses audio video clock running at 50 MHz. The PCM clock and LR clock are fed to the PCM player and S/PDIF clock is fed to the S/PDIF player.

35.1.7 Decode mode

The audio decoder decodes MPEG1 layer 1 and 2 streams only. During the decoding process the AUD_DEC_STATUS register holds information such as bit rate, sampling frequency and audio mode. The audio decoder is ready to decode after de-assertion of either hard reset or soft reset. No bits have to be set to start the decoding process.

35.1.8 Interrupt register

The audio decoder can be configured to generate an interrupt in a variety of conditions. Enabling the interrupt is done by setting the corresponding bit in the AUD_DEC_INT_ENABLE register. Writing 0 to ENB_INT (bit0) disables all the interrupts. When an interrupt is detected the source of the interrupt can be retrieved by reading the AUD_DEC_INT_STATUS register. The interrupt can be cleared by writing 1 to the corresponding bit of the AUD_DEC_INT_CLEAR register.

35.1.9 PCM beep tone

The PCM beep tone is a special mode used for set-top boxes. It generates a triangular signal of variable frequency and amplitude on the left and right channels. The intended use is for satellite dish alignment (22 kHz) and not for generating a beep tone through the television speaker.

In STx5119, the audio decoder does not generate the beep tone. The PCM file corresponding to the beep tone is initialized in memory by the software. The CPU moves the data stream corresponding to the beep tone to the PCM player using the FDMA.

36 Audio decoder registers

Addresses are provided as the AudioBaseAddress + offset.

The AudioBaseAddress is:

0x2070 0000.

37 PCM player

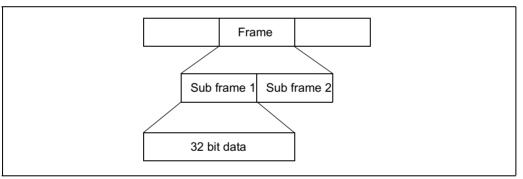

The PCM player plays audio data stored in memory using the appropriate STBus interface. The player is compliant with Phillips I^2S and SONY audio data format. The number of serial outputs is variable from 1 to 5 depending upon the number of stereo audio channels.

Figure 151: System diagram

The basic PCM element consists of a sub-frame made up of a 32 bit word (up to 32 audio data bits). A frame consists of two sub-frames.

Figure 152: PCM stream

Input

The PCM player receives data and control words from the STBus interface via a simple register interface with a request/acknowledge for clock synchronization.

Output

The output consists of five serial stereo data channels, a bit clock and an LR clock.

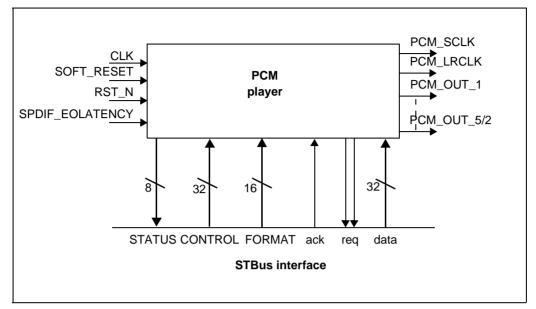

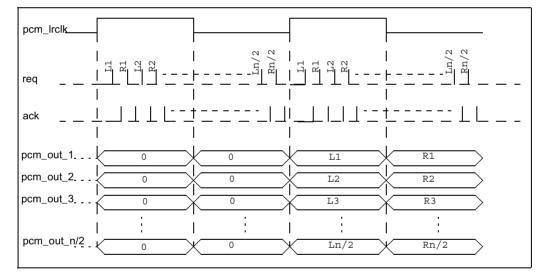

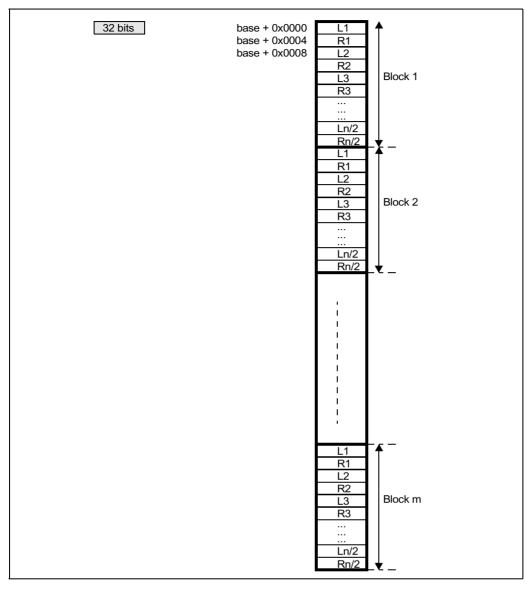

Figure 154: Signal timing

The first sample sent by the STBus interface to the PCM player block is a LEFT sample.

7939391A

37.1 Data

The PCM data consists of up to 24 bits audio samples.

Data is located on an external memory, and should be aligned and formatted as shown in Figure 156.

Description:

[31:0] SUBFRAME DATA

39 S/PDIF player

39.1 Overview

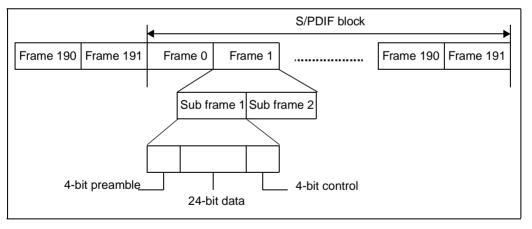

The S/PDIF player plays PCM audio data or audio-encoded bit streams stored in memory in the S/PDIF format using the STBus interface. The player is compliant with IEC-60958 for audio data and IEC-61937 for compressed audio data. The block receives data from memory using the FDMA, formats the data and sends it out on the S/PDIF output pin.

Figure 157: System diagram

The basic S/PDIF element is a subframe that consists of a 32-bit word (a 4-bit preamble, up to 24 audio data bits and 4 control bits). A frame consists of two subframes and a block consists of 192 frames.

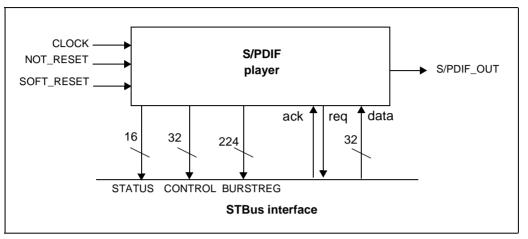

Figure 158: S/PDIF stream

S/PDIF Signals 39.1.1

The S/PDIF player receives data and control words from the STBus interface using a simple register interface with a request/acknowledge signal for clock synchronization. Figure 159 show the S/PDIF player architecture.

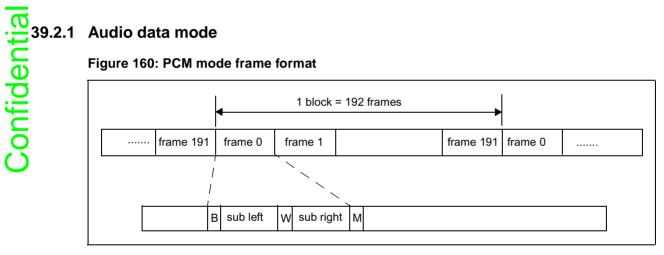

39.2 Audio data mode or encoded mode

Audio data mode

Figure 160: PCM mode frame format

PCM null data

Δ7/

The PCM null data is sent on the S/PDIF output when:

- in S/PDIF audio data mode (SPDIF CTRL[2:0] = 011) and an underflow is detected (the ACK signal not asserted after a request for data), or
- in S/PDIF MUTE with PCM null data mode (SPDIF_CTRL[2:0] = 001).

The PCM null data is generated by hardware, and the VUC data is read in burst registers (refer to Section 40.1.1: Burst registers on page 397).

Switching between modes

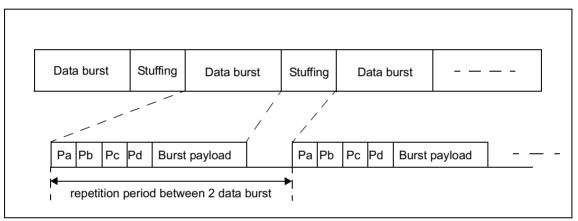

When an underflow occurs before the end of a block, PCM null data is sent until the end of the S/PDIF block is reached. When the end of the block is reached, a check is made to see if data has been received.

- If data has been received: PCM data is sent to the S/PDIF output.
- If data has not been received (still in underflow active): another complete block (192 frames) of null data is sent to the S/PDIF output.
- When S/PDIF MUTE mode is selected before the end of a block, the switch to mute mode is only effective (PCM null data send on S/PDIF output) when the end of a frame is reached. Wait until the end of the block to switch back to S/PDIF audio data mode.
- The switch to S/PDIF off mode is only effective when the end of a block is reached.

39.2.2 Encoded mode

Data burst

Figure 161: Data burst format

The repetition period between two data bursts is defined in SPDIF_BURST_LEN[31:16] register.

Stuffing

The stuffing can be made by software or hardware. The selection is made by bit 14 of the SPDIF_CTRL register.

Soft stuffing

The software enabled stuffing data is received by the S/PDIF player through the data input port. The data received is as following:

3132	 16	15	 4	3	0
0	 0	0	 0	VUC	0
0	 0	0	 0	VUC	0
0	 0	0	 0	VUC	0
0	 0	0	 0	VUC	0

Pause data burst

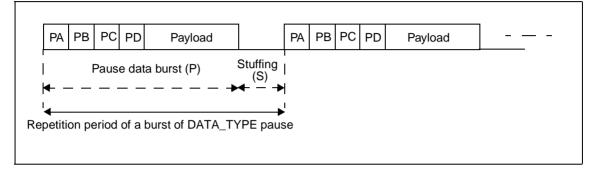

The pause data burst is sent to the S/PDIF output if:

- in S/PDIF encoded mode (SPDIF_CTRL[2:0] = 100), an underflow is detected (the ACK signal not asserted) and an end of data burst is reached,
- in S/PDIF MUTE with pause burst mode (SPDIF_CTRL[2:0] = 010).

The pause data-burst is generated by the hardware.

For generating the pause burst, the PA, PB, PC, PD and the VUC information is read in the burst registers (refer to Section 40.1.1: *Burst registers* on page 397).

Figure 162: Pause burst format

The repetition period between two pause bursts is defined in the SPDIF_BURST_LEN[15:0] register.

The number of pause burst (P + S) repetition periods are defined in the SPDIF_PAUSE_LAT[31:16] register.

- If set to 1, the hardware sends one P+S on the S/PDIF output, before looking if the operation mode has changed, or if data has been received by the S/PDIF player (underflow).
- If set to 3, the hardware sends three P+S on the S/PDIF output, before looking if the operation mode has changed or if data have been received by the S/PDIF player (underflow).

The channel status bit number of the first PA sent on the S/PDIF output is stored in the SPDIF_STATUS register.

- If SPDIF_PAUSE_LAT[31:16] register = 1 each time PA is sent to the S/PDIF output, the PA_C_BIT_NUMBER field of the SPDIF_STATUS register is updated with that channel's status bit number.
- If the SPDIF_PAUSE_LAT[31:16] register = 3 when the first PA, the fourth, the seventh PA (and so on) are sent to the S/PDIF output, the PA_C_BIT_NUMBER field of the SPDIF_STATUS register is updated with the channel status bit number.

The application uses this information to resynchronize the next data to be sent to the S/PDIF player.

Switch between modes

- When an underflow occurs before the end of a data burst, null data is sent until the end of the data burst is reached. When the end of the data burst is reached, a check is made to see if data has been received.
 - If data has been received a data burst is sent on the S/PDIF output.
 - If data has not been received (still in underflow active) a pause data burst is sent on the S/PDIF output.
- When S/PDIF MUTE mode is selected before the end of a data burst, the switch to mute mode is only effective (pause data burst sent on the S/PDIF output) when the end of the data burst is reached. Wait until the end of the pause data burst to switch back to S/PDIF enhanced mode.
- The switch to S/PDIF off mode is only effective when the end of the data burt or pause data burst is reached.

39.2.3 Byte swap

Depending on the endianness of the received data, a byte swap may be required. By setting bit 13 of the SPDIF_CTRL register to 1, a byte swap is applied in encoded mode between bits [31:24] and bits [23:16]. No byte swap is performed on bits [15:0].

Byte swap is only performed on the data received on the data input bus (PA, PB, PC, PD and burst payload). When playing pause bursts, PA, PB, PC and PD are read in the SPDIF_PA_PB and SPDIF_PC_PD burst registers and no byte swap is performed on PA, PB, PC or PD.This means that these four 16-bit words need to be stored in their associated burst registers with the corrected endianness.

3 Data

The S/PDIF data is composed of audio samples or encoded data plus a set of S/PDIF control words (user data, channel status and validity flag).

Data is located in external memory and should be aligned and formatted as shown in Figure 163.

STBus 32-bit word	31	24	23	16	15	8	7	0		
S/PDIF 24-bit word	MSB		24 k	oits data		LSB	0000	Control		
S/PDIF 20-bit word	MSB		20 bits	data	LSB	0000	0000	Control		
S/PDIF 16-bit word*	MSB	16 bi	ts data	LSE	0000	0000	0000	Control		
				Validity flag 3 2 1 0 User data bit Channel status bit 0						

Figure 163: STBus data

Note: This is the only format for S/PDIF encoded mode.

39.4 Interrupts

There are five registers for interrupt management:

- SPDIF_INT_STATUS, read-only interrupt status register,
- SPDIF_INT_STATUS_CLR, clear interrupt status,
- SPDIF_INT_EN, read-only interrupt enable register,
- SPDIF_INT_EN_SET, set interrupt enable,
- SPDIF_INT_EN_CLR, clear interrupt enable.

Table 98 gives the mapping of the SPDIF_INT_STATUS bits.

Table 98: S/PDIF player block interrupt mapping

SPDIF_INT_STATUS	Interrupt source
SPDIF_INT_STATUS[0]	Underflow
SPDIF_INT_STATUS[1]	End of data burst
SPDIF_INT_STATUS[2]	End of block
SPDIF_INT_STATUS[3]	End of latency
SPDIF_INT_STATUS[4]	End of PD data burst
SPDIF_INT_STATUS[5]	Memory block fully read
SPDIF_INT_STATUS[6]	End of PD pause burst

Each time an interrupt occurs, the relevant SPDIF_INT_STATUS bit is set to 1. If the corresponding bit of the SPDIF_INT_EN_SET register is also set to 1 the interrupt request output signal is asserted.

When the system has received an interrupt request, the reading of the SPDIF_INT_STATUS register shows which source has generated the interrupt.

Once the interrupt has been taken into account, software can set the corresponding bit of the SPDIF_INT_STATUS_CLR register to 1 to de-assert the interrupt request output signal and to clear the corresponding bit of the SPDIF_INT_STATUS register.

39.5 Soft reset

When software sets the SPDIF_SOFTRESET register to 1, the GPFIFO completes the transaction in progress and any data inside the FIFO after the soft reset must be considered invalid. After the soft reset the SPDIF_SOFTRESET register is reset to 0.

40 S/PDIF player and GPFIFO registers

Addresses are provided as the S/PDIFBaseAddress + offset.

The S/PDIFBaseAddress is:

0x2060 0000.

41 Audio DAC

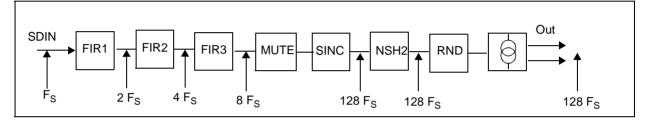

41.1 Description

This audio digital-to-analog converter (DAC) is a high performance stereo audio converter operating at 256 Fs system clock. This DAC accepts 24-bit input data in I²S format from the PCM player macro block and converts it into a differential current analog output signal. This signal is then filtered and transformed into a voltage output signal by an external analog filter.

The data converter uses a sigma-delta architecture which includes a second order noise shaper. The sigma delta modulator is followed by a 5-bit DAC to achieve at least 18-bit resolution.

This DAC can operate at sampling frequencies of 32, 44.1 and 48 kHz as well as any other audio frequencies below 48 kHz.

Figure 164: Digital flow

Confidential

The input stream SDIN derived from the audio decoder, sampled at Fs, is first interpolated by two and then filtered by a 75th order FIR filter, FIR1. This signal, at 2 Fs, is interpolated by two and filtered by a 20th order FIR filter, FIR2. The signal, at 4 Fs, can be soft muted by the MUTE block, and enters the SINC filter which interpolates by 32. The noise shaper then transforms this signal to five bits. A randomizer then expands the data to a thermometer code and permutes the sources to avoid mismatch between the 32 current sources.

The audio frequency synthesizer, within the clock generator, provides a system clock at 256 x Fs which is divided down internally to produce all other clocks.

41.2 Input signals and output pins

41.2.1 Supplies

The audio DAC utilizes two supply levels, 1.2 V and 3.3 V for different stages. Supplies are split into digital and analog for noise immunity as appropriate.

41.2.2 Output signals

Input/output	Pin name	Description
Output	OUTRPLUS	Right differential positive analog output
	OUTRMINUS	Right differential negative analog output
	OUTLPLUS	Left differential positive analog output
	OUTLMINUS	Left differential negative analog output
	VBGOUT	Bandgap voltage output. This pin should be connected to an external 10uF capacitor (analog ground)

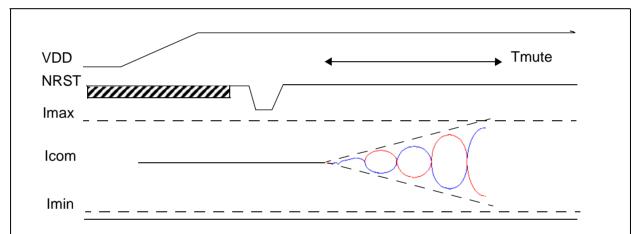

Table 100: Audio DAC output signals

41.2.3 Reset

A low level on NOT_RESETIN or a reset of bit Interconnect Config Control D[NRST] puts the system in reset mode by initializing internal counters and control registers.

At reset, the audio DAC is disabled. Figure 165 shows the recommended sequence.

Figure 165: Reset timing

41.3 Soft mute

The mute function is controlled by the soft mute input. In this mode the output current (OUTRPLUS, OUTRMINUS, OUTLPLUS and OUTLMINUS) is attenuated to 96 dB. When the output current reaches the common mode current lcom, the current sources are switched off one after the other in order to decrease the output current. Once this sequence is complete, the analog part can be powered down. The total time for the mute/unmute sequence is at least 1920 sampling periods each. This mute function is also controllable through Interconnect Config Control Reg D.

Figure 166: Soft mute sequence

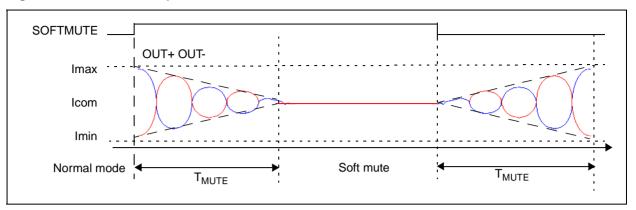

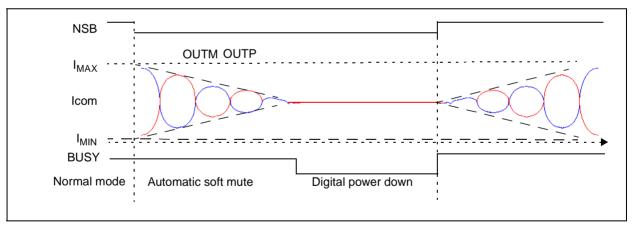

Table 101: Soft mute timings

Symbol	Parameter	Min	Тур	Max	Unit			
T _{MUTE}	Total time for mute/unmute sequence							
	Normal mode		1920		T _{LR}			
	Double mode		960	1024	T _{LR}			

4 Digital and analog power down

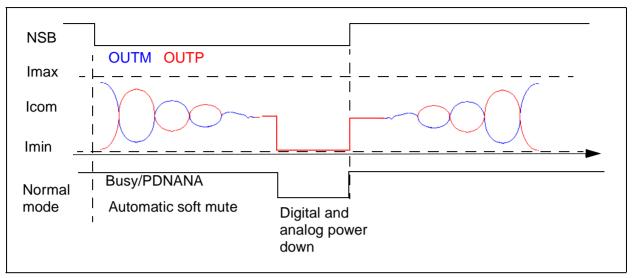

To minimize power consumption the digital and analog parts can be put into power down mode separately. In the digital power up (NSB = 1) and in power down (NSB = 0) there is an automatic soft mute.

Figure 167: Digital power-down sequence

For a digital and analog power down at the same time a pop noise can be heard with the high end application schematic. To avoid the pop noise the very high end application board schematic should be used.

41.5 Output stage filtering

The audio DAC provides differential current source outputs for each channel. The use of a differential mode interface circuit is recommended to achieve the best signal to noise ratio performance. A single-ended mode interface circuit can be used, by grounding pins OUTLMINUS/OUTRMINUS, but this is not recommended as the resulting signal to noise ratio is less than 90 dB.

An external 1% resistor RREF should be connected to pin IREFOUT of the DAC. A typical value for RREF is 200 Ohm. RREF should always be higher than 175 Ohm to get a proper bandgap functionality. Also it is recommended to filter the bandgap reference through a 10uF capacitor to the analog ground.

42 Flexible DMA (FDMA)

The flexible DMA (FDMA) is a general-purpose direct memory access controller capable of supporting 16 independent DMA channels. It is used to perform block moves thus reducing the load on the CPU. Moves may be from memory-to-memory or between memory and paced latency-critical real-time targets.

The FDMA supports the following features:

- 16 independent DMA channels,
- transfer of information to or from aligned or unaligned data structures of up to 4 Gbytes in the following organizations:
 - single location (0D),
 - incrementing linear arrays (1D),
 - incrementing rectangular arrays (2D),
- transfer units of 1 to 32 bytes,
- programmable opcodes for paced transfer,
- paced or free running timing models,
- support for up to 30 request generating peripherals,
- a single interrupt which signals completion of:
 - a list of transfers,
 - each transfer of a node in a list,
- little endian data organization,
- linked list control which allows,
 - a set of DMA transfers to be sequenced,
 - complex operations such as scatter-gather without CPU intervention,
- special channel configurations for:
 - PES parsing/SCD,
 - memory-to-memory moves or free running transfers,
 - paced¹ transfers,
 - S/PDIF output.

407/543

^{1.} A channel is paced if an external request causes a single data unit to be transferred per request. The FDMA may require multiple requests to complete the operation.

42.1 Channel structures

There are three types of channel in the STx5119 FDMA:

- standard 0D, 1D, 2D and paced memory channels,
- an SCD/PES parsing channel,
- an S/PDIF channel.

All the channels use linked lists of FDMA operations stored in memory. SCD/PES parsing channels require additional control data which is written to FDMA data memory before the channel is started.

Each linked list is composed of a series of nodes in main memory. Each node is a data structure containing parameters that describe an FDMA transfer.

Typically a linked list of nodes is set up in main memory, the pointer to the first node is written to the FDMA and the channel is started. This bootstraps the list, loading the first entry node and continuing until completion of all the DMAs in the list.

On completion of a node the channel may generate an interrupt indicating completion and/or trigger a channel update.

A channel update causes the next node in the list to be loaded from memory. The location of the node structure in memory is given by a pointer.

This may be used to extend the channel's operation to support features such as scatter gather sequences, or building DMA sequences with only the final completion requiring CPU intervention via an interrupt.

To emulate a ping-pong buffer using a 2 node (looped) linked list it is possible to generate an interrupt on completion of one node while moving directly to the next (interrupt but no pause). In other words the interrupt does not stall the channel.

2.1.1 DMA transfer units

The FDMA uses the most efficient opcode for the requested transaction. The supported unit size for the paced transfer is programmable at 1×4 , 2×2 , 4, 8, 16 and 32 bytes. Byte enables are used for nonword aligned cases.

Paced transfers must be aligned to their opcode size.

42.1.2 Alignment

Confidential

Note:

The node structures must be aligned to a 32 byte boundary.

The most efficient data transfers are aligned to a 128 byte boundary and the number of bytes transferred should be a multiple of 32.

For paced channels, the paced-side data must be aligned to the paced opcode (OP32 must be 32byte aligned, OP16 must be 16 byte aligned and so on). The memory side of a paced transfer must be 32-byte aligned. There are no alignment restrictions for the memory side of S/PDIF transfers.

For SCD/PES parsing the PES buffer must be treated as linear. A circular PES buffer can be described using two linked nodes. The PES buffer must be 128 byte aligned. The ES buffer and Start codes list buffers must also be 32 byte aligned.

42.2 FDMA timing model

42.2.1 Free-running

The FDMA is free-running. Once a channel is started, the operations occur without requiring a request to begin or control the timing of the transfer. It continues to operate without further intervention until disabled, or the transfer is complete.

This is the model generally used for memory-to-memory moves.

A sleep mechanism can be used to slow down these accesses.

42.2.2 Paced

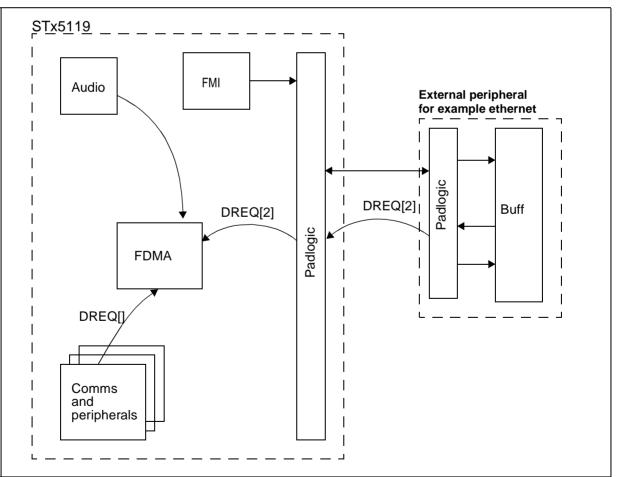

A channel is paced if a single data unit is transferred to or from a peripheral upon request. The request may be associated with either the source or destination memory location.

The FDMA supports up to 30 physical request signals.

Only the DREQ request protocol is supported. The peripheral uses the STBus request to the data FIFO to determine that a requested transfer has been acknowledged by the FDMA and it clears the DREQ signal (when applicable).

The FDMA implements a hold off mechanism to ensure that it ignores the DREQ for a certain period of time after having serviced a data request:

Figure 169: FDMA request routing

Block	Block port/signal name	FDMA requests	Description		
External	DREQ[0:1]	1,2	DMA reqs from pads		
Audio	AUDIO_CD_REQ	3	CD req from Decoder		
	AUDIO_DECO_REQ	4	Req. to read decoded data		
	AUDIO_PCMO_REQ	5	Req. to write data to PCM player		
	AUDIO_SPDIF	6	Req. to write data to SPDIF player		
COMMS/UART (x2)	UART[0]_RX_HALF_FULL	7	UART Rx. FIFO Half full		
	UART[1]_RX_HALF_FULL	8			
	UART[0]_TX_HALF_EMPTY	9	UART Rx. FIFO Half Empty		
	UART[1]_TX_HALF_EMPTY	10	7		
COMMS/SSC (x2)	SSC[0]_RXBUFF_HALF_FULL	11	SSC Rx. FIFO Half full		
	SSC[1]_RXBUFF_HALF_FULL	12	7		
	SSC[0]_TXBUFF_HALF_EMPTY	13	SSC Rx. FIFO Half Empty		
	SSC[1]_TXBUFF_HALF_EMPTY	14	7		

Table 102: FDMA internal handshakes

42.2.3 SCD/PES parsing channel

An SCD/PES parsing channel runs until the list is complete or a pause at the end of a node is encountered.

Confidential 42.2.4 S/PDIF channel

The S/PDIF channel is treated as a standard paced channel.

42.2.5 PCM player channel

The PCM player channel is treated as a standard paced channel.

42.2.6 Audio decoder channels

Two channels support the audio decoder. One channel is memory to paced that writes the compressed data to the audio decoder. The other channel is paced to memory that writes the decoded data to the memory.

42.3 **Operating the FDMA**

Communication between the CPU and the FDMA is achieved through two 32-bit mailbox registers plus one command and status (FDMA_CMD_STAT) register per channel.

- The command mailbox register sends commands from the CPU to the FDMA.
- The interrupt mailbox sends interrupts from the FDMA to the CPU.

Two bits of each mailbox register are associated with each channel.

- The CPU sets bits in the command mailbox and clears bits in the interrupt mailbox.
- The FDMA clears bits in the command mailbox and sets bits in the interrupt mailbox.

Interrupts and flags are generated for each channel by setting mask bits in the mailbox register. Any masked nonzero bits in the mailbox either raise an interrupt (interrupt mailbox) or generate a flag in the FDMA (command mailbox).

There are three commands for each channel, set in the command mailbox:

- START: start and initialize channel n (no initialize if the channel is restarting after a PAUSE),
- PAUSE: pause channel n,
- FLUSH: flush and pause channel n.

42.3.1 Channel arbitration

Types of transfer are not associated with channel numbers, but are specified in the node's control word (see REQ_MAP field). Each of the 16 independent channels competes for the service of the FDMA.

- The paced channels have the highest priority.
- SCD/PES parsing have medium priority.
- Memory-to-memory moves use the remaining bandwidth and are arbitrated using a round-robin scheme.

When more than one paced channel requests servicing, the channel with the highest external request line has the highest priority.

42.3.2 Starting a channel

In idle mode the FDMA waits for any of the channels to be started. All channels require at least one node in main memory which contain all or part of the necessary information required to execute a DMA transfer. For SCD/PES parsing, additional information is required and should be written to the appropriate registers in the FDMA data memory before the channel is started. See Section 42.4.3: SCD/PES parsing on page 416.

The channel initialization procedure is given below.

- 1. Create a linked list of nodes describing the transfer in main memory.
- 2. For SCD/PES parsing write the additional parameters as follows:
 - 2.1 initial write pointer: SC_WRITE,
 - 2.2 size of the start code list: SC_SIZE,
 - 2.3 elementary stream buffer parameters: ESBUF_TOP, ESBUF_READ, ESBUF_WRITE, ESBUF_BOT).
- 3. Write the pointer to the first node and command data in the FDMA_CMD_STAT register for the channel.
- 4. Write the START command to the command mailbox.

When a command is flagged in the command mailbox the FDMA processes the command on the appropriate channel and then clears the bits in the command mailbox. The FDMA_CMD_STAT register provides the current status of the channel and a pointer to the current node in the linked list.

Note: The FDMA_CMD_STAT register must only be written to if the channel is idle or paused.

Before the START command is issued the channel status and the address of the last node to have been loaded is provided from the FDMA_CMD_STAT register for the channel.

A channel can be restarted (no channel initialization) if it was previously paused. When a channel is restarted a pointer to a node in memory should not be written to FDMA_CMD_STAT.

Note: Only one command for a channel can be sent in each direction until it is acknowledged. This means the CPU or FDMA must check the mailbox before writing a new command. Only if the bits corresponding to the channel are 0 (the previous message was acknowledged) is it safe to send another message.

42.3.3 Pausing a transfer

A transfer may be paused either by specifying this in the node structure or by sending a PAUSE command to the FDMA. A pause is interpreted as a requirement to pause the channel at the earliest possible safe moment. The FDMA stops sending new requests over the STBus but continues to process outstanding return data (data is processed and placed into the FDMA's internal buffers but not sent to destination). A paced channel's DREQ is not processed once the pause command has been received.

The FDMA signals when the channel is paused by writing the status in the channels FDMA_CMD_STAT register and setting the channel's bit in the interrupt mailbox (only if the PAUSE command is issued by the host). The number of bytes remaining to be transferred for the current node and the pointer to the current node are available from the channel's FDMA_COUNT and FDMA_CMD_STAT registers respectively.

42.3.4 Flushing a channel

When a pause command is issued, the FDMA may still contain valid data inside its internal buffers. If this data is required, a FLUSH command is issued instead of a PAUSE. When the FLUSH command is received, the FDMA pauses the channel but also flushes any data it may have in the internal buffers. Once the internal buffers have been flushed, the channel is returned to the idle state and the host is interrupted. Flush only applies to paced channels where the source of data is paced.

Note: It is possible to flush a channel even if it is in the paused state

42.3.5 Restarting a paused transfer

Once a channel has been paused, the host may restart the channel by issuing the START command. The FDMA continues processing the node from where it was paused.

When a channel is restarted a pointer to a node does not need to be written to FDMA_CMD_STAT.

42.3.6 Abort

Confidentia

Note:

Once a channel is paused, the host can start a new transfer simply by starting the channel with a new linked list of nodes. This effectively aborts the previous transfer.

42.3.7 Error handling

Errors are signalled by the FDMA setting the channel's error bit in the interrupt mailbox register. This generates an interrupt request if the mailbox error bit is masked. The interrupt mailbox shows which channel is signalling the error.

The type of error is specified in the FDMA_CMD_STAT register for the channel (bits 2, 3 and 4). The error bits in the FDMA_CMD_STAT register are only valid if the error bit in the interrupt mailbox is set, otherwise they should be ignored.

If the FDMA cannot continue processing, it pauses after signalling the error. The status is read from FDMA_CMD_STAT to determine whether the channel was paused or whether it is still running.

The interrupt is acknowledged by clearing both the error bit and the interrupt bit in the interrupt mailbox.

42.4 Setting up FDMA transfers

An FDMA channel transfers units of data from a source data structure to a destination data structure using the de-coupling internal DRAM.

After channel initialization, the FDMA acknowledges the START command by clearing the channel's command mailbox register bits and begins the transfer by loading nodes one at a time from main memory. The transfer specified by each node is executed before the next node is loaded. The transfer continues until:

- the transfer is complete, or
- the FDMA is required to pause at the end of a node, or
- there is an error condition and it is not possible to continue.

A node is complete when all NBYTES of the node have been transferred. At the end of each node (specified in the NODE_NBYTES register). The FDMA may do one of the following:

- continue on to the next node without interrupting the host, or
- interrupt the host and continue on to the next node, or
- interrupt the host and pause the channel until the host tells the FDMA to continue, or
- interrupt the host and return the channel to the idle state if there are no more nodes to process

Note: It is mandatory for the FDMA to interrupt the host on completion of the last node.

42.4.1 Memory-to-memory moves and free running transfers

This channel type is described entirely by the generic node structure. Data is organized in a number of different ways, including:

- single location (0D),
- incrementing linear arrays (1D),
- incrementing rectangular arrays (2D).

All possible combinations of source and destination data organization is possible for a transfer. For example from 0D source to 2D destination or 1D source to 2D destination.

All data structures are specified with respect to an origin or initial byte address and the address of subsequent transfers is calculated from the origin using information provided in the node.

Single location (0D)

If the data structure is fixed or single location, the same address is used throughout the transfer and no further information is needed. This is set in each node by NODE.CONTROL.SRC_INC = CONSTANT SOURCE for a 0D source, or NODE.CONTROL.DST_INC = CONSTANT SOURCE for a 0D destination.

Incrementing (1D)

A structure is 1D if NODE.NBYTES= NODE.LENGTH or if NODE.STRIDE = NODE.LENGTH.

For any 1D transfer the address is incremented by one byte until NODE.NBYTES bytes are transferred.

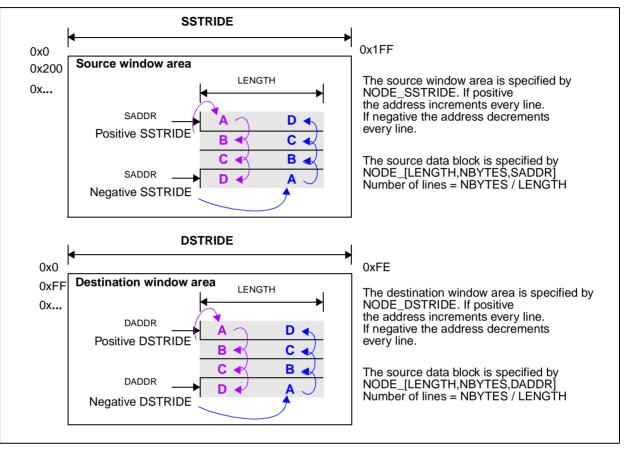

In the case of a incrementing transfer from address NODE.SADDR of NODE.NBYTES bytes, the following bytes at the following addresses are transferred:

NODE.SADDR to NODE.SADDR + (NODE.NBYTES - 1)

Rectangular array (2D)

If NODE.NBYTES \neq NODE.LENGTH and abs(NODE.[S|D]STRIDE) \neq NODE.LENGTH then the transfer is 2D

Figure 170: 2D transfers

The bytes transferred during a 2D transfer are specified by:

```
for (y=0;y<(NODE.NBYTES / NODE.LENGTH);y++)</pre>
```

```
for (x=0;x<NODE.LENGTH;x++)</pre>
```

```
*(char*)(NODE.DADDR+x+NODE.DSTRIDE*y) = *(char*)(NODE.SADDR+x+NODE.SSTRIDE*y)
```

Note: To do a 1D to 2D transfer (or a 2D to 1D transfer) the source or destination stride must be specified (depending on whether the source or destination should be 1D) to be the same as the length.

Source	Destination Buffer							
buffer	0D	1D	2D					
0D	L = source location size	L = source location size	L = source location size					
	SS = 0	SS = 0	SS = 0					
	DS = 0	DS = L	DS = destination stride					
1D	L = source location size	L = NBytes	L = destination line length					
	SS = L	SS = 0	SS = L					
	DS = 0	DS = 0	DS = destination stride					
2D	L = source location size	L = source line length	L = destination line length					
	SS = source stride	SS = source stride	SS = source stride					
	DS = 0	DS = L	DS = destination stride					

Table 104: Definitions

Acronym	Description	Variable Name
L	Length	Length
SS	Source stride	SourceStride
DS	Destination stride	DestinationStride
NBytes	Number of bytes to transfer	NumberBytes

42.4.2 Paced transfers

The FDMA transfers data from or to paced peripherals, using the data memory as a temporary store. Paced channels are triggered by a DREQ signal from a peripheral device. The memory side of the transfer is described by the generic node structure (Section 42.1: *Channel structures* on page 408). The paced side is described by the FDMA_REQ_CONTROL[n] parameters (). The node's control word (NODE_CONTROL) specifies a REQ_MAP number describing which DREQ line and FDMA_REQ_CONTROL word to use for the transfer.

Once the channel is started, the FDMA writes and reads data from the paced channel when the DREQ for the channel is asserted. A holdoff mechanism ensures that a DREQ is not sampled immediately after it has been serviced (the holdoff period is specified in the

FDMA_REQ_CONTROL registers). Latency in the interconnect may cause the DREQ to remain high for some time after it has been serviced. The channel's circular FIFO in FDMA data memory is filled or emptied of data depending on whether the level of data is below or above the threshold (typically half the FIFO size).

Data is stored temporarily in a circular buffer in data memory before being transferred to the destination.

Paced peripheral is data source

When the paced peripheral is the data source, data is fetched from the peripheral when it's DREQ is asserted. When the read request is sent to the peripheral, the DREQ is masked using the holdoff mechanism (the holdoff period is specified in the FDMA_REQ_CONTROL word). This prevents the DREQ from being sampled high again immediately after it has been serviced. The data is then stored in the channel's circular buffer. If the buffer level exceeds the threshold, data is read from the buffer and sent to the destination.

Paced peripheral is destination

Data is read from the source and placed into the circular buffer in data memory when the buffer level falls below the threshold. When the DREQ for a paced peripheral is asserted, data is fetched from the circular buffer and sent to the peripheral. The holdoff mechanism is used to mask the DREQ to prevent it being sampled high again immediately after it has been serviced (see Section 4.16: Hold off mechanism on page 33).

42.4.3 SCD/PES parsing

A channel configured as a SCD/PES parsing channel fetches data from a linear buffer in main memory (a circular buffer should be handled with a pair of nodes) and detects any start codes within three user-defined ranges: a PES start code range and two elementary stream (ES) start code ranges. The SCD/PES parsing node provides a pointer to the PES buffer and the number of bytes which must be read from the buffer. During SCD/PES parsing, the FDMA processes each node and generates a list of start codes depending on the start code ranges specified in the node. At the end of each node the FDMA can interrupt the host and/or pause the transfer.

The initial write pointer and size of the start code list (SC_WRITE, SC_SIZE) must be provided, as well as the ES buffer parameters to describe the ES buffer (ESBUF_TOP, ESBUF_READ, ESBUF_WRITE, ESBUF_BOT). Also specified are the three start code ranges and whether the range should be detected.

The SCD/PES parsing starts when a START command is issued for the channel. The FDMA can be requested to interrupt the host by setting the INT_ENB and PAUSE_ENB bits in the node's control word.

If PES start code detection is enabled (DETECT_ENABLE in PES_CONTROL = 1), the PES is parsed and the payload (ES) is written to a circular ES buffer. If PES start code detection is disabled, PES headers are not parsed and removed, but ES start code detection is carried out and the output is stored in the circular ES buffer. The start codes list contains the start code and the memory address of the start code (not the offset from the top of the ES buffer). The PTS can also optionally be output to the start codes list.

When one-shot mode is selected for a start code range (ONESHOT_MODE in $SCn_CONTROL = 1$), the FDMA detects the first start code in the range. It then ignores the next start codes in the range until the first start code in the other range is found. The FDMA then searches for a start code in the first range once again.

When detection of the PES start code range is enabled (DETECT_ENABLE = 1), the PES stream is parsed, the PES headers removed and the elementary stream is written to the ES buffer. If detection of PES start codes is disabled, start code detection is executed on the incoming ES stream and the stream is copied to the ES buffer.

When PES range detection is enabled using DETECT_ENABLE, the PTS can also be written to the start codes list. For the two ES start code ranges the detection mode must be specified (single-shot or continuous). Three additional data regions specify these parameters (a fourth is reserved for the S/PDIF channel). Each node then references one of these regions. This allows up to three streams to be processed by multiplexing them on the same channel. Each node in the list describes a transfer for one stream.

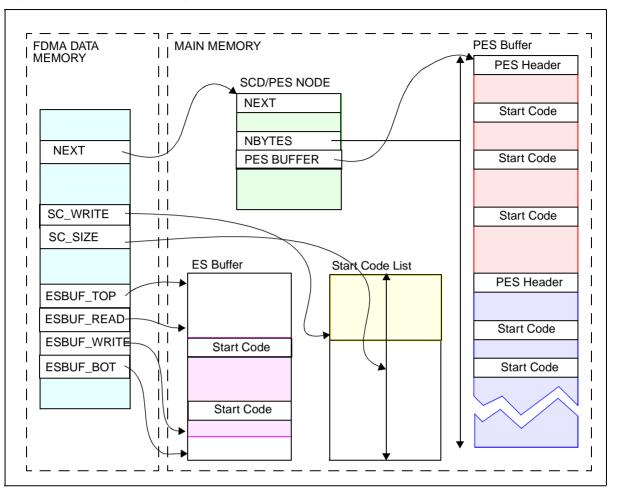

Figure 171: SCD/PES parsing data structures

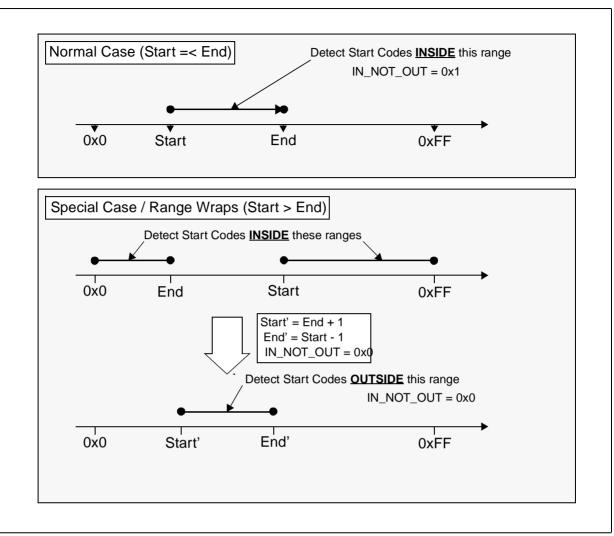

Specifying start code ranges

When specifying the start code ranges the host must ensure that RANGE_END >= RANGE_START (see PES_CONTROLn and SCn_CONTROLm). In order to respect this rule when the range wraps, a start code range [Start,End] must be transformed into a nonwrapping range using the following procedure:

```
if(Start <= End)
{
    IN_not_OUT = 1
    RANGE_START = Start
    RANGE_END = End
}
else
{
    IN_not_OUT = 0
    RANGE_START = End + 1
    RANGE_END = Start -1
}</pre>
```

Confidential

Figure 172: Start code range setup

Overflow handling

There may be occasions when either the start codes list or the ES buffer overflows.

When the start codes list overflows the FDMA sets bit 0 in the SC_WRITE register for the channel and continues parsing the PES data and outputting data to the ES buffer. However, no start code is added to the list. If the incoming data is ES, it is simply copied to the ES buffer.

When the ES buffer overflows, the FDMA signals this by setting bit 0 in the ESBUF_WRITE register for the channel. The FDMA ignores the overflow condition and continues processing data thereby overwriting data already in the ES buffer.

Start codes list

The start codes list is output as a linear array of data structures. Each structure is four words in size (16 bytes) and may contain either start code data or PTS data. A label specifies whether the structure contains a start code or PTS. To know how many entries have been placed in the start codes list, the driver must read SC_WRITE and compare it with the value it had written at the start of the transfer. The difference, divided by 4 gives the number of entries in the start codes list.

42.4.4 Audio data output through S/PDIF player

The S/PDIF channel is a paced channel in which the FDMA formats data before outputting the data to the S/PDIF player. S/PDIF output involves PTI, ST20, FDMA and the S/PDIF player. The ST20 parses the PES stream coming from PTI and sets up a transfer on the S/PDIF channel.

Each node in the linked list contains the data to enable the FDMA to fetch data from a buffer, format it and output it when the S/PDIF player raises a DREQ. The node's source address points to the start of the audio frame. The node also contains the information required by the FDMA to format the incoming data. The formatted data is output to the S/PDIF player when it raises the DREQ. In order to correctly describe the data transfers for a single burst, it may be necessary to use a linked list of two or more nodes. The BURST_END bit indicates to the FDMA when the last set of data for the burst is being transferred. This allows the FDMA to automatically generate the correct stuffing to complete a burst. The node following a node in which BURST_END = 1 is considered the first node of the next burst.

Valid nodes

The S/PDIF channel nodes' control word contains a node valid bit. This bit indicates whether the node is valid. If a node is loaded by FDMA and the valid bit is not set, the FDMA completes the current burst by sending stuffing data and then return the channel to idle. The CPU is interrupted.

This mechanism only works correctly if the words are read in order (from lowest address to highest) when fetching the node from LMI. This is because the audio driver is expected to fill the node structure and validate it once the node structure has been completed.

End of burst

The BURST_END bit, part of the S/PDIF node's CONTROL parameter is used to indicate that the node describes the last node of an S/PDIF burst. The FDMA uses this to know when it should start to output stuffing. The node following a node with BURST_END = 0x1 is considered the start of a burst.

Output of stuffing

The FDMA needs to output stuffing to the S/PDIF player when the data for a burst is finished but the end of the burst hasn't been reached. The FDMA keeps a count of the outstanding frames to output for a burst. When an end of burst node is received and all the data associated with that node is transferred or when an invalid node is received, the FDMA outputs stuffing until the outstanding frames counter goes to zero.

43 Flexible DMA (FDMA) registers

All node registers are nonvolatile. Other registers are volatile.

SCD and PES parsing channels require additional data. These transfer types are described by nodes which include an additional data region number. Each additional data region is composed of 16 words and the format is transfer-type dependent.

Register addresses are provided as the FDMABaseAddress + offset.

The FDMABaseAddress is:

0x20D0 0000.

Description:	When a channel is running, its FDMA_CMD_STAT register is written by the FDMA and always contains the current state of the channel. The interrupt mailbox register is used by the FDMA to interrupt the CPU. When the CPU receives an interrupt the mailbox should be read to determine which channel generated the interrupt and the interrupt acknowledged by clearing the channel's bit in the interrupt mailbox. The channel's status can be read from the FDMA_CMD_STAT register. The FDMA may raise an interrupt either if this is specified in the node or if a pause command is issued by the host. If the host issues a pause command but does not want to be interrupted by the FDMA when the channel enters the paused state, it should								

command is issued by the host. If the host issues a pause command but does not want to be interrupted by the FDMA when the channel enters the paused state, it should unmask the interrupt by clearing the channels mask bit in the interrupt mailbox. Each channel has two bits associated with it in the interrupt mailbox, an interrupt bit and an error bit.

- [n x 2] CHANNELn: If bit n = 1 message pending for channel n
- $[n \times 2 + 1]$ **ERRORn:** If bit n = 1 there is an error for channel n

44 Infrared transmitter/receiver

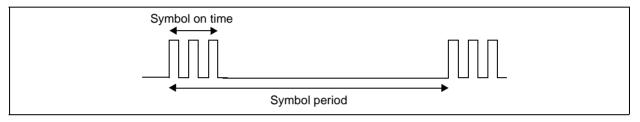

44.1 Overview

The infrared (IR) transmitter/receiver is an ST20 peripheral. For each symbol transmitted, the software driver determines the symbol period and the symbol on time of the IR pulse, and transfers these parameters into a 8-word deep FIFO. The IR transmitter/receiver then generates coded symbols using an internally generated subcarrier clock.

The parameters symbol period and symbol on time are illustrated in Figure 173.

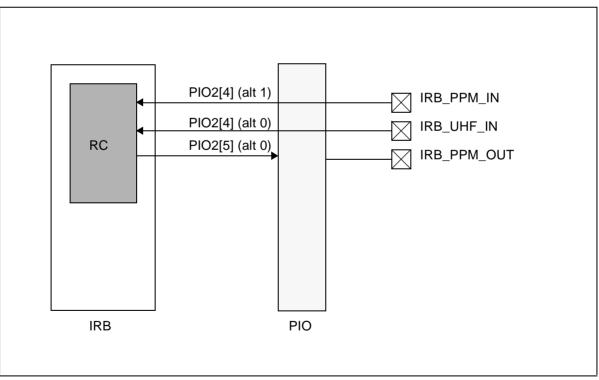

The incoming signal must be detected, and the subcarrier must be suppressed, externally. Only the symbol envelope can be used by the IR and UHF processors. It is sampled at 10 MHz and the sample values are transferred into the input buffer in microseconds.

Figure 173: IR transmitter/receiver symbol

The connectivity of the IR transmitter/receiver is given in Figure 174.

44.2 Functional description

The IR transmitter/receiver transmits infrared data and receives both IR and UHF data. The IR and UHF receivers are independent and identical, except that the IR receiver does not use the noise filter. Both receivers are simultaneously active. The IR transmitter/receiver supports RC (remote control) codes only.

Figure 175 shows the IR transmitter/receiver block diagram in a typical circuit configuration.

In the transmitter there are two programmable dividers to generate the prescaled clock and the subcarrier clock. The subcarrier clock sets the resolution for the transmitted data. Both receivers contain a sampling rate clock, which samples the incoming data, and is programmed to 10 MHz.

FIFOs buffer both the transmitter output and the receivers' inputs to avoid timing problems with the CPU. Interrupts can be set on the FIFOs' levels to prevent input data overrun and output data underrun.

There are two 8-word FIFOs in the RC transmitter and two 8-word FIFOs in each RC receiver. The eighth element in each 8-word FIFO is used internally and is not accessible to the STBus. Therefore, the 8-word FIFO is empty when there are seven empty words and full when it contains seven words. At all times, the fullness level of the 8-word FIFO is given in the corresponding status register.

The pair of FIFOs, for symbol period and symbol on time, in each submodule should be treated as a set and must be consecutively accessed for read or for write. They share a common pointer which is incremented only when they have been accessed correctly. Repeated reads on one FIFO always give the same data, and repeated writes always overwrite the previous data.

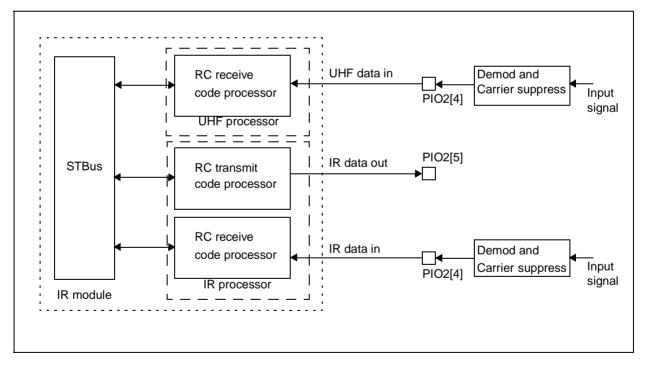

Figure 175: IR transmitter/receiver block diagram and implementation

UHF and IR data in functions are programmed as alternative 0 and alternative 1 functions of PIO2. See Table 7: *PIO2 alternative functions* on page 34.

44.2.1 RC transmit code processor

RC codes are generated by programming the transmit frequency and writing the symbol information into a FIFO which is then read internally and the data processed to provide a serial PWM data stream. The transmit interrupt is set on a preselected FIFO level. An interrupt and a flag in the status register indicates an underrun condition (that is, an empty FIFO). RC data transmission is disabled by setting bit 0 of register IRB_TX_EN_IR to 0.

The transmit interrupt is set by register IRB_TX_INT_EN_IR, on one of three FIFO levels:

- when seven words are empty (buffer is empty),
- when four words are empty (buffer is half full),
- when at least one word is empty.

The transmit status is cleared automatically when new data is written to the registers IRB_TX_SYM_PERIOD_IR and IRB_TX_ON_TIME_IR. Register bits IRB_TX_INT_STATUS_IR[5:4] give the FIFO's fullness status. To clear the interrupt status clear the corresponding clear bit location in the IRB_TX_INTERRUPT_CLEAR_IR register.

Note: The IRB_TX_STATUS_IR register reflects the true status of the block.

The frequency of the subcarrier is set by programming the registers IRB_TX_PRE_SCALER_IR and IRB_TX_SUB_CARRIER_IR.

The symbol period, in subcarrier cycles, is programmed in the register IRB_TX_SYM_PERIOD_IR and the on time of the IR pulse is written to the register IRB_TX_ON_TIME_IR. These two registers are eight-word FIFOs. They must be programmed sequentially as a pair to increment the write pointer and be ready for the next data. Transmission is enabled by setting register IRB_TX_EN_IR bit 0 to 1. If new data is not written before the last symbol in the buffer is transmitted, no RC codes are generated. The output is driven to logic 0

4.2.2 RC receive code processor

This section describes the UHF data and the IR data receivers. They are independent and identical. The 10 MHz sampling clock is common to both receivers and is set by register IRB_RX_SAMPLING_RATE_COMMON. This register is programmed with the value 5 for a 50 MHz infrared transmitter/receiver system clock, or with the value 6 for a 60 MHz clock.

Each receiver processes the incoming RC code symbol envelope and stores the values symbol period and symbol on time (in microseconds) in an eight-word FIFO buffer, until the data can be read by the microcontroller.

The receive interrupt is set by register IRB_RX_INT_EN to one of the following three FIFO levels:

- at least one word is available to be read,
- four or more words are available to be read (FIFO half full),
- seven words are available to be read (FIFO full).

and the register IRB_TX_INT_STATUS_IR bit 1 is set.

The receive status (IRB_RX_STATUS_IR) is cleared when the registers IRB_RX_SYM_PERIOD and IRB_RX_ON_TIME have been read. They must be read consecutively, as a pair, to increment the FIFO read pointer. Bits 4 and 5 of the register IRB_RX_INT_STATUS give the fullness level of the FIFO. To clear the interrupt status clear the corresponding bit in the IRB_RX_INTERRUPT_CLEAR_IR register.

If the FIFO is full and has not been read before the arrival of new data, then this data is lost and a receive overrun flag is set in the status register IRB_RX_INT_STATUS. No new data is written

to the FIFO while this condition exists. To reset the overrun flag the operations below must be performed.

- 1. Read at least one word from each of the receive FIFO registers, IRB_RX_SYM_PERIOD and IRB_RX_ON_TIME.
- 2. The RXOVERRUNSTATUS bit is automatically cleared but if the interrupt was enabled the corresponding interrupt status is cleared by writing 0x01 to the IRB_RX_INTERRUPT_CLEAR_IR register.

The last symbol is detected using a time out condition whose value is stored in microseconds in register IRB_RX_MAX_SYM_PERIOD. If no pulse has been received during this time then the last word in the FIFO IRB_RX_SYM_PERIOD has a value 0xFFFF. If the value of register IRB_RX_INT_EN bit 1 (LASTSYMBOLIRQENABLE bit) is 1, then an interrupt is triggered and the status register IRB_RX_INT_STATUS bit 1 is set. The status bit is cleared automatically when the last value in the FIFO has been read.

Note: There are separate receive interrupt status and interrupt clear locations for IR and UHF. When register IRB_RX_INT_EN bit 0 is set to 0 then both the FIFO level interrupt and the last symbol interrupt are inhibited.

RC data reception can be disabled by setting register IRB_RX_EN bit 0 to 0. However, both receivers are normally always enabled.

44.2.3 Noise suppression filter

This filter is programmable in the IR and UHF receiver using registers IRB_RX_NOISE_SUPPRESS_WIDTH_IR or IRB_RX_NOISE_SUPPRESS_WIDTH_UHF. Any pulses, either high or low, having a value in microseconds of less than the programmed width, are assumed to be noise and, therefore, suppressed.

The noise suppression filter can be disabled by writing 0x00 to register IRB_RX_NOISE_SUPPRESS_WIDTH_UHF.

44.2.4 Reception in low power mode

In low power mode the system clock is switched off and the 27 MHz clock is active. Before entering low power mode the 27 MHz operation should be enabled by setting the clock select bit in IRB_RX_CLOCK_SELECT. It is not mandatory to have an exact 27 MHz clock but only a clock running during low power mode if filtering is needed on wakeup trigger pulses. If filtering of wakeup pulses is not required then this clock need not be used and should be tied to a logic level (either 0 or 1). Care must be taken that the software does not executes a clock switch.

Wakeup trigger pulse generation

A wakeup trigger pulse is generated on the wakeup outputs RC_WAKEUP_TRIGGER and UHF_WAKEUP_TRIGGER on receipt of an active pulse on RC data or UHF data respectively. The polarity of the wake up trigger pulse is active high, irrespective of the active polarity of corresponding input.

The RC_WAKEUP_TRIGGER and UHF_WAKEUP_TRIGGER are generated only after being filtered by the noise suppression filter. Filtering can be disabled by programming the noise suppression width to 0x00. In low power mode the system clock should be switched off. To facilitate filtering by the noise suppression filter, the noise suppression filter should be switched to work with the 27 MHz clock by setting the CLOCK_SELECT bit in the IRB_RX_CLOCK_SELECT register to 1. In 27 MHz mode, if a value n is programmed in the noise suppression filter, all the pulses smaller than n / 27 μ s are treated as noise and filtered. This is because the 27 MHz clock is fed directly to the noise suppression filter without any prescaler division.

The wakeup trigger pulse is generated only if the IRB is enabled and the corresponding receive section is enabled by setting the appropriate bit in the receive enable register.

Wakeup interrupt

Once the device is in low power mode, the infra-red remote control device is restored to normal mode by using the wakeup feature.

The wakeup mechanism is shown in Figure 176. In low power mode the signal LOW_POWER_MODE is at logic 1. This signal can be the output of the low power controller's LOWPOWEROUT signal or any other signal which remains statically high when the chip is in low power mode.

On the rising edge of the trigger pulse the flip-flops hold logic 1 and a logic 1 is asserted on the corresponding wakeup interrupt pin. These pins are routed to the interrupt controller which in turn generates the wakeup by interrupt to the low power controller. The low power controller then restores the normal operation.

45 Infrared transmitter/receiver registers

This section describes the RC transmitter and receiver registers, the RC and UHF receiver and control registers and the noise suppression registers of the IR transmitter/receiver. Although the IR RC receiver and UHF RC receiver registers are held at different addresses, their register descriptions are identical and are only given once for each pair of registers.

Addresses are provided as the *IRBBaseAddress* + offset.

The IRBBaseAddress is:

0x2081 8000.

46 Asynchronous serial controller (ASC)

46.1 Overview

The asynchronous serial controller, also referred to as the UART interface, provides serial communication between the STx5119 and other microcontrollers, microprocessors or external peripherals. The STx5119 provides two ASCs, one of which is used as the smartcard controller.

Parity generation, 8- or 9-bit data transfer and the number of stop bits is programmable. Parity, framing, and overrun error detection is provided to increase the reliability of data transfers. The transmission and reception of data can simply be double-buffered, or 16-deep FIFOs may be used. Handshaking is supported on both transmission and reception. For multiprocessor communication, a mechanism to distinguish the address from the data bytes is included. Testing is supported by a loop back option. A dual mode 16-bit baudrate generator provides the ASC with a separate serial clock signal.

Each ASC supports full duplex, asynchronous communication, where both the transmitter and the receiver use the same data frame format and the same baudrate. Data is transmitted on the transmit data output pin TXD and received on the receive data input pin RXD.

Each ASC can be set to operate in smartcard mode for use when interfacing to a smartcard.

46.2 Control

The ASC_n_CONTROL register controls the operating mode of the ASC. It contains control and enable bits, error check selection bits, and status flags for error identification.

Serial data transmission or reception is only possible when the baudrate generator run bit (RUN) is set to 1. When the RUN bit is set to 0, TXD is 1. Setting the RUN bit to 0 immediately freezes the state of the transmitter and receiver and should only be done when the ASC is idle.

lote: Programming the mode control field (MODE) to one of the reserved combinations results in unpredictable behavior.

The ASC can be set to use either double-buffering or a 16-deep FIFO on transmission and reception.

46.2.1 Resetting the FIFOs

The registers ASC_n_TXRESET and ASC_n_RXRESET have no actual storage associated with them. A write of any value to one of these registers resets the corresponding FIFO.

46.2.2 Transmission and reception

Serial data transmission or reception is only possible when the baudrate generator run bit (RUN) is set to 1. A handshaking protocol is supported on both transmission and reception, using CTS and RTS signals.

A transmission is started by writing to the transmit buffer register ASC_n_TXBUFFER. Data transmission is either double buffered or uses a FIFO (selectable in the ASC_n_CONTROL register), therefore a new character may be written to the transmit buffer register before the transmission of the previous character is complete. This allows characters to be sent back to back without gaps.

Data reception is enabled by the receiver enable bit (RXENABLE) in the ASC_n_CONTROL register. After reception of a character has been completed, the received data and, if provided by the selected operating mode, the parity error bit, can be read from the receive buffer register, ASC_n_RXBUFFER.

Confidential Note:

Reception of a second character may begin before the received character has been read out of the receive buffer register. The overrun error status flag (OVERRUNERROR) in the status register, ASC_n_STATUS, is set when the receive buffer register has not been read by the time the reception of a second character is completed. The previously received character in the receive buffer is overwritten, and the ASC_n_STATUS register is updated to reflect the reception of the new character.

The loop back option (selected by the LOOPBACK bit in the ASC_n_CONTROL register) internally connects the output of the transmitter shift register to the input of the receiver shift register. This may be used to test serial communication routines at an early stage without having to provide an external network.

46.3 Data frames

Data frames may be 8-bit or 9-bit, with or without parity and with or without a wake up bit. The data frame type is selected by setting the MODE bit field in the control register.

The transmitted data frame consists of three basic elements:

- start bit,
- data field (8 or 9 bits, least significant bit (LSB) first, including a parity bit or wake up bit, if selected),
- stop bits (0.5, 1, 1.5 or 2 stop bits).

😽 46.3.1 8-bit data frames

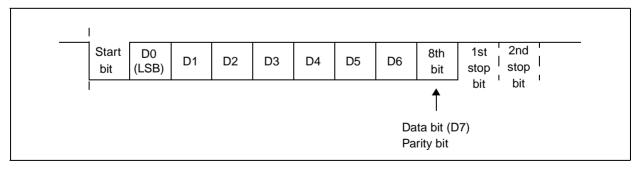

Figure 177 illustrates an 8-bit transmitted data frame. 8-bit frames may use one of the following formats:

- eight data bits D[0:7] (MODE set to 001),
- seven data bits D[0:6] plus an automatically generated parity bit (MODE set to 011).

Parity may be odd or even, depending on the PARITYODD bit in the ASC_n_CONTROL register. If the modulo 2 sum of the seven data bits is 1, then the even parity bit is set and the odd parity bit is cleared.

In receive mode the parity error flag (PARITYERROR) is set if a wrong parity bit is received. The parity error flag is stored in the 8th bit (D7) of the ASC_n_RXBUFFER register. The parity error bit is set high if there is a parity error.

Figure 177: 8-bit Tx data frame format

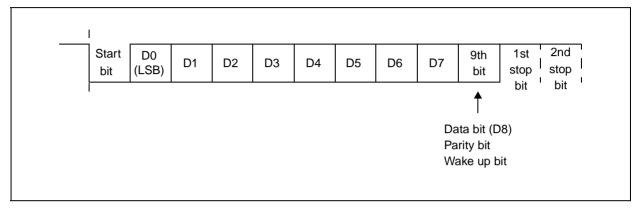

46.3.2 9-bit data frames

STx5119

Figure 178 illustrates a 9-bit transmitted data frame. 9-bit data frames use of one of the following formats:

- nine data bits D[0:8] (MODE set to 100),
- eight data bits D[0:7] plus an automatically generated parity bit (MODE set to 111),
- eight data bits D[0:7] plus a wake up bit (MODE set to 101).

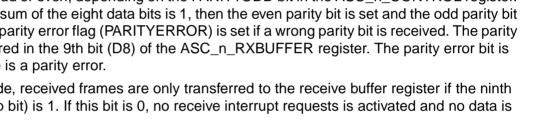

Figure 178: 9-bit Tx data frame format

Parity may be odd or even, depending on the PARITYODD bit in the ASC_n_CONTROL register. If the modulo 2 sum of the eight data bits is 1, then the even parity bit is set and the odd parity bit is cleared. The parity error flag (PARITYERROR) is set if a wrong parity bit is received. The parity error flag is stored in the 9th bit (D8) of the ASC_n_RXBUFFER register. The parity error bit is set high if there is a parity error.

In wake up mode, received frames are only transferred to the receive buffer register if the ninth bit (the wake up bit) is 1. If this bit is 0, no receive interrupt requests is activated and no data is transferred.

This feature may be used to control communication in multiprocessor systems. When the master processor wants to transmit a block of data to one of several slaves, it first sends out an address byte which identifies the target slave. An address byte differs from a data byte in that the additional ninth bit is 1 for an address byte and 0 for a data byte, so no slave is interrupted by a data byte. An address byte interrupts all slaves (operating in 8-bit data plus wake up bit mode), so each slave can examine the eight least significant bits (LSBs) of the received character, which is the address. The addressed slave switches to 9-bit data mode, which enables it to receive the data bytes that are coming (with the wake up bit cleared). The slaves that are not being addressed remain in 8-bit data plus wake up bit mode, ignoring the data bytes which follow.

46.4 Transmission

Transmission begins at the next baudrate clock tick, provided that the RUN bit is set and data has been loaded into the ASC_n_TXBUFFER. If the CTSENABLE bit is set in the ASC_n_CONTROL register then transmission only occurs when CTS is high.

The transmitter empty flag (TXEMPTY) indicates whether the output shift register is empty. It is set at the beginning of the last data frame bit that is transmitted, that is, during the first comms clock cycle of the first stop bit shifted out of the transmit shift register.

The loop back option (selected by the LOOPBACK bit of the ASC_n_CONTROL register) internally connects the output of the transmitter shift register to the input of the receiver shift register. This may be used to test serial communication routines at an early stage without having to provide an external network.

A transmission ends with stop bits (1 is output on TXD). When the SCENABLE bit in the ASC_n_CONTROL register is 0, the length of these stop bits is determined by the setting of the STOPBITS field of the ASC_n_CONTROL register. This can either be for 0.5, 1, 1.5 or 2 baud clock periods. In smartcard mode, when the SCENABLE bit in the ASC_n_CONTROL register is 1, the number of stop bits is determined by the value in ASC_n_GUARDTIME.

46.4.1 Transmission with FIFOs enabled

The FIFOs are enabled by setting the FIFOENABLE bit of the ASC_n_CONTROL register. The output FIFO is implemented as a 16-deep array of 9-bit vectors. Values to be transmitted are written to the output FIFO by writing to ASC_n_TXBUFFER.

The TXFULL bit of the ASC_n_STATUS register is set when the transmit FIFO is considered full, that is, when it contains 16 characters. Further writes to ASC_n_TXBUFFER fail to overwrite the most recent entry in the output FIFO. The TXHALFEMPTY bit of the ASC_n_STATUS register is set when the output FIFO contains eight or fewer characters.

Values are shifted out of the bottom of the output FIFO into a 9-bit output shift register in order to be transmitted. If the transmitter is idle (that is, the output shift register is empty) and something is written to the ASC_n_TXBUFFER so that the output FIFO becomes nonempty, the output shift register is immediately loaded from the output FIFO and transmission of the data in the output shift register begins at the next baudrate tick.

When the transmitter is just about to transmit the stop bits, and if the output FIFO is nonempty, the output shift register is immediately loaded from the output FIFO, and the transmission of this new data begins as soon as the current stop bit period is over (that is, the next start bit is transmitted immediately following the current stop bit period). If the output FIFO is empty at this point, the output shift register becomes empty. Thus back to back transmission of data can take place. Writing anything to ASC_n_TXRESET empties the output FIFO.

After changing the FIFOENABLE bit, it is important to reset the FIFO to empty (by writing to the ASC_n_TXRESET register), or garbage may be transmitted.

46.4.2 Double buffered transmission

Double buffering is enabled and the FIFOs disabled by writing 0 to the FIFOENABLE bit of the ASC_n_CONTROL register. When the transmitter is idle, the transmit data written into the transmit buffer ASC_n_TXBUFFER is immediately moved to the transmit shift register, thus freeing the transmit buffer for the next data to be sent. This is indicated by the transmit buffer empty flag (TXHALFEMPTY) being set. The transmit buffer can be loaded with the next data while transmission of the previous data is still going on.

When the FIFOs are disabled, the TXFULL bit is set when the buffer contains 1 character, and a write to ASC_n_TXBUFFER in this situation overwrites the contents. The TXHALFEMPTY bit of the ASC_n_STATUS register is set when the output buffer is empty.

46.5 Reception

Reception is initiated by a falling edge on the data input pin RXD, provided that the RUN and RXENABLE bits of the ASC_n_CONTROL register are set.

Controlled data transfer can be achieved using the RTS handshaking signal provided by the UART. The sender checks the RTS to ensure the UART is ready to receive data. In double buffered reception RTS goes high when ASC_n_RXBUFFER is empty, in FIFO controlled operation it goes high when RXHALFFULL is zero.

The RXD pin is sampled at 16 times the rate of the selected baudrate. A majority decision of the first, second and third samples of the start bit determines the effective bit value. This avoids erroneous results that may be caused by noise.

If the detected value of the first bit of a frame is not 0, then the receive circuit is reset and waits for the next falling edge transition at the RXD pin. If the start bit is valid, that is 0, the receive circuit continues sampling and shifts the incoming data frame into the receive shift register. For subsequent data and parity bits, the majority decision of the seventh, eighth and ninth samples in each bit time is used to determine the effective bit value. The effective values received on RXD are shifted into a 10-bit input shift register.

For 0.5 stop bits, the majority decision of the third, fourth, and fifth samples during the stop bit is used to determine the effective stop bit value. For 1 and 2 stop bits, the majority decision of the seventh, eighth, and ninth samples during the stop bits is used to determine the effective stop bit values. For 1.5 stop bits, the majority decision of the 15th, 16th, and 17th samples during the stop bits is used to determine the effective stop bit value.

Reception is stopped by clearing the RXENABLE bit of ASC_n_CONTROL. Any currently received frame is completed including the generation of the receive status flags. Start bits that follow this frame are not recognized.

6.5.1 Hardware error detection

To improve the safety of serial data exchange, the ASC provides three error status flags in the ASC_n_STATUS register which indicate if an error has been detected during reception of the last data frame and associated stop bits.

• The parity error bit (PARITYERROR) in the ASC_n_STATUS register is set when the parity check on the received data is incorrect.

In FIFO operation parity errors on the buffers are ORed to yield a single parity error bit.

- The framing error bit (FRAMEERROR) in the ASC_n_STATUS register is set when the RXD pin is not 1 during the programmed number of stop bit times (see Section 46.5). In FIFO operation the bit remains set while at least one of the entries has a frame error.
- The overrun error bit (OVERRUNERROR) in the ASC_n_STATUS register is set when the input buffer is full and a character has not been read out of the ASC_n_RXBUFFER register before reception of a new frame is complete.

These flags are updated simultaneously with the transfer of data to the receive input buffer.

Frame and parity errors

The most significant bit (bit 9 of 0 to 9) of each input entry, records whether or not there was a frame error when that entry was received (that is, one of the effective stop bit values was 0). The FRAMEERROR bit of the ASC_n_STATUS register is set when the input buffer (double buffered operation), or at least one of the valid entries in the input buffering (FIFO controlled operation), has its most significant bit set.

If the mode is one where a parity bit is expected, then the next bit (bit 8 of 0 to 9) records whether there was a parity error when that entry was received. It does not contain the parity bit that was received. For 7-bit + parity data frames the parity error bit is set in both the eighth (bit 7 of 0 to 9) and the ninth (bit 8 of 0 to 9) bits. The PARITYERROR bit of ASC_n_STATUS is set when the

input buffer (double buffered operation), or at least one of the valid entries in the input buffering (FIFO controlled operation), has bit 8 set.

When receiving 8-bit data frames without parity (see Section 46.3.1 on page 462), the ninth bit of each input entry (bit 8 of 0 to 9) is undefined.

46.5.2 Input buffering modes

FIFO enabled reception

The FIFOs are enabled by setting the FIFOENABLE bit of the ASC_n_CONTROL register. The input FIFO is implemented as a 16-deep array of 10-bit vectors (each 9 down to 0). If the input FIFO is empty, that is, no entries are present, the RXBUFFULL bit of the ASC_n_STATUS register is set to 0. If one or more FIFO entries are present, the RXBUFFULL bit of the ASC_n_STATUS register is set to 1. If the input FIFO is not empty, a read from ASC_n_RXBUFFER gets the oldest entry in the input FIFO.

The RXHALFFULL bit of the ASC_n_STATUS register is set when the input FIFO contains more than eight characters. Writing anything to ASC_n_RXRESET empties the input FIFO. As soon as the effective value of the last stop bit has been determined, the content of the input shift register is transferred to the input FIFO (except during wake up mode, in which case this happens only if the wake up bit, bit 8, is 1). The receive circuit then waits for the next falling edge transition at the RXD pin.

The OVERRUNERROR bit of the ASC_n_STATUS register is set when the input FIFO is full and a character is loaded from the input shift register into the input FIFO. It is cleared when the ASC_n_RXBUFFER register is read.

After changing the FIFOENABLE bit, it is important to reset the FIFO to empty by writing to the ASC_n_RXRESET register; otherwise the state of the FIFO pointers may be garbage.

Double buffered reception

Double buffered operation is enabled and the FIFOs disabled by writing 0 to the FIFOENABLE bit of the ASC_n_CONTROL register. This mode can be seen as equivalent to a FIFO controlled operation with a FIFO of length 1 (the first FIFO vector is in fact used as the buffer). When the last stop bit has been received (at the end of the last programmed stop bit period) the content of the receive shift register is transferred to the receive data buffer register (ASC_n_RXBUFFER). The receive buffer full flag (RXBUFFULL) is set, and the parity error (PARITYERROR) and framing error (FRAMEERROR) flags are updated at the same time, after the last stop bit has been received (that is, at the end of the last stop bit programmed period), the flags are updated even if no valid stop bits have been received. The receive circuit then waits for the next falling edge transition at the RXD pin.

46.5.3 Time out mechanism

The ASC contains an 8-bit time out counter. This reloads from ASC_n_TIMEOUT whenever one or more of the following is true:

- ASC_n_RXBUFFER is read,
- the ASC is in the middle of receiving a character,
- ASC_n_TIMEOUT is written to.

If none of these conditions hold the counter decrements towards 0 at every baudrate tick.

The TIMEOUTNOTEMPTY bit of the ASC_n_STATUS register is 1 when the input FIFO is not empty and the time out counter is zero.

The TIMEOUTIDLE bit of the ASC_n_STATUS register is 1 when the input FIFO is empty and the time out counter is zero.

7939391A

The effect of this is that whenever the input FIFO has got something in it, the time out counter decrements until something happens to the input FIFO. If nothing happens, and the time out counter reaches zero, the TIMEOUTNOTEMPTY bit of the ASC_n_STATUS register is set.

When the software has emptied the input FIFO, the time out counter resets and starts decrementing. If no more characters arrive, when the counter reaches zero the TIMEOUTIDLE bit of the ASC_n_STATUS register is set.

46.6 Baudrate generation

Each ASC has its own dedicated 16-bit baudrate generator with 16-bit reload capability. The baudrate generator has two possible modes of operation.

The ASC_n_BAUDRATE register is the dual function baudrate generator and reload value register. A read from this register returns the content of the counter or accumulator (depending on the mode of operation); writing to it updates the reload register.

If the RUN bit of the ASC_n_CONTROL register is 1, then any value written in the ASC_n_BAUDRATE register is immediately copied to the counter/accumulator. However, if the RUN bit is 0 when the register is written, then the counter/accumulator is not reloaded until the first comms clock cycle after the RUN bit is 1.

The baudrate generator supports two modes of operation, offering a wide range of possible values. The mode is set via the BAUDMODE bit in the ASC_n_CONTROL register. Mode 0 is a simple counter driven by the comms clock whereas Mode 1 uses a loop back accumulator. Mode 0 is recommended for low baudrates (below 19.2 Kbaud), where its error deviation is low, and Mode 1 is recommended for baudrates above 19.2 Kbytes.

46.6.1 Baudrates

The baudrate generator provides an internal oversampling clock at 16 times the external baudrate. This clock only ticks if the RUN bit of the ASC_n_CONTROL register is set to 1. Setting this bit to 0 immediately freezes the state of the ASC's transmitter and receiver.

Mode 0

When the BAUDMODE bit in the ASC_n_CONTROL register is set to 0, the baudrate and the required reload value for a given baudrate can be determined by the following formulae:

 $BaudRate = \frac{f_{comms}}{16 \times ASCBaudRate}$

ASCBaudRate =

f_{comms} 16 x *BaudRate*

where:

- ASCBaudRate represents the content of the ASC_n_BAUDRATE reload value register, taken as an unsigned 16-bit integer,
- f_{comms} is the frequency of the communications clock, see Chapter 18: System services on page 123).

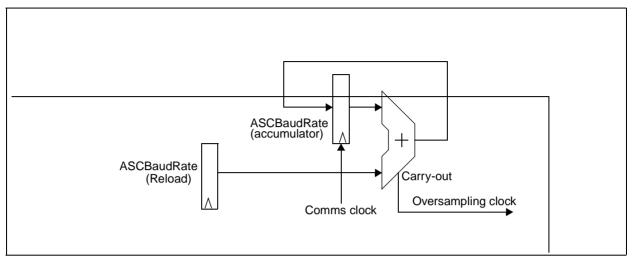

The baudrate counter is clocked by the comms clock. It counts downwards and can be started or stopped by the RUN bit in the ASC_n_CONTROL register. Each underflow of the timer provides one oversampling baudrate clock pulse. The counter is reloaded with the value stored in its 16-bit reload register each time it underflows.

Writes to the ASC_n_BAUDRATE register update the reload register value. Reads from the ASC_n_BAUDRATE register return the current value of the counter.

Mode 1

When the BAUDMODE bit in the ASC_n_CONTROL register is set to 1, the baudrate is controlled by the circuit in Figure 179.

Figure 179: Baudrate in mode 1

The CPU writes go to ASC_n_BAUDRATE to the reload register. The CPU then reads from ASC_n_BAUDRATE and returns the value in the accumulator register. Both registers are 16 bits wide and are clocked by the comms clock (PLL_CLOCK[2]).

Writing a value of *ASCBaudRate* to the ASC_n_BAUDRATE register results in an average oversampling clock frequency of:

 $\frac{ASCBaudRate \ x \ f_{comms}}{2^{16}}$

So the baudrate is given by:

BaudRate =
$$\frac{ASCBaudRate \times f_{comms}}{16 \times 2^{16}}$$

This gives good granularity, and hence low baudrate deviation errors, at high baudrate frequencies.

46.7 Interrupt control

Each ASC contains two registers that are used to control interrupts, the status register (ASC_n_STATUS) and the interrupt enable register (ASC_n_INTENABLE). The status bits in the ASC_n_STATUS register show the cause of any interrupt. The interrupt enable register allows certain interrupt causes to be masked. Interrupts occur when a status bit is 1 (high) and the corresponding bit in the ASC_n_INTENABLE register is 1.

The ASC interrupt signal is generated from the OR of all interrupt status bits after they have been ANDed with the corresponding enable bits in the ASC_n_INTENABLE register, as shown in Figure 180.

The status bits cannot be reset by software because the ASC_n_STATUS register cannot be written to directly. Status bits are reset by operations performed by the interrupt handler:

- transmitter interrupt status bits (TXEMPTY and TXHALFEMPTY) are reset when a character is written to the transmitter buffer,
- receiver interrupt status bit (RXBUFFULL) is reset when a character is read from the receive buffer,
- PARITYERROR and FRAMEERROR status bits are reset when all characters containing errors have been read from the receive input buffer,
- The OVERRUNERROR status bit is reset when a character is read from ASC_n_RXBUFFER.

-46.7.1 Using the ASC interrupts when FIFOs are disabled (double buffered operation)

The transmitter generates two interrupts; this provides advantages for the servicing software. For normal operation (that is, other than the error interrupt) when FIFOs are disabled the ASC provides three interrupt requests to control data exchange via the serial channel:

- TXHALFEMPTY is activated when data is moved from ASC_n_TXBUFFER to the transmit shift register,
- TXEMPTY is activated before the last bit of a frame is transmitted,
- RXBUFFULL is activated when the received frame is moved to ASC_n_RXBUFFER.

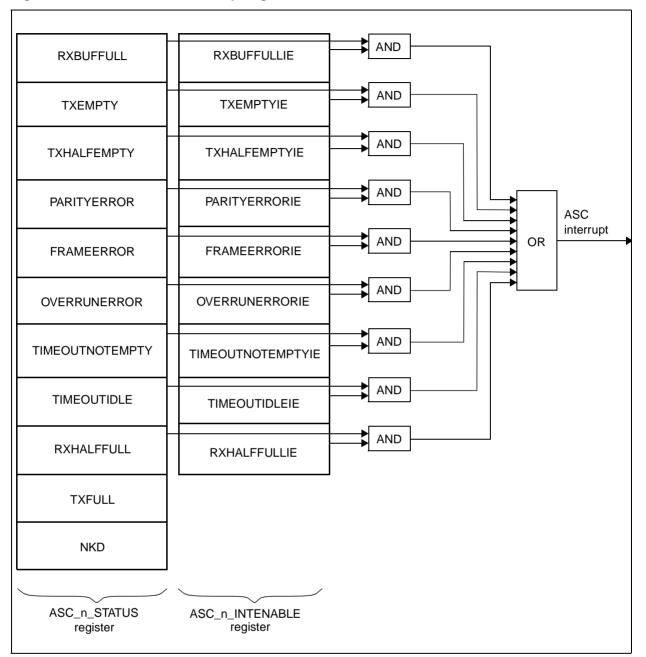

Figure 180: ASC status and interrupt registers

As shown in Figure 180, TXHALFEMPTY is an early trigger for the reload routine, while TXEMPTY indicates the completed transmission of the data field of the frame. Therefore, software using handshake should rely on TXEMPTY at the end of a data block to make sure that all data has really been transmitted.

For single transfers it is sufficient to use the transmitter interrupt (TXEMPTY), which indicates that the previously loaded data has been transmitted, except for the last bit of a frame.

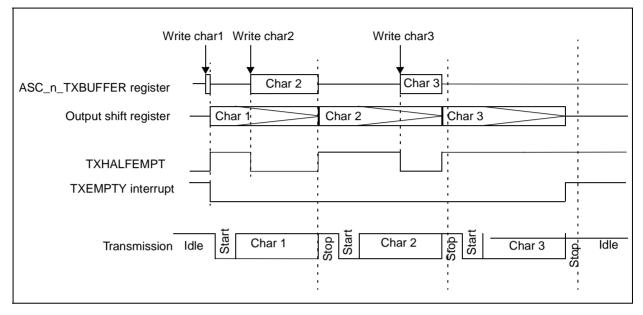

For multiple back to back transfers it is necessary to load the next data before the last bit of the previous frame has been transmitted. The use of TXEMPTY alone would leave just one stop bit time for the handler to respond to the interrupt and initiate another transmission. Using the output buffer interrupt (TXHALFEMPTY) to signal for more data allows the service routine to load a complete frame, as ASC_n_TXBUFFER may be reloaded while the previous data is still being transmitted.

46.7.2 Using the ASC interrupts when FIFOs are enabled

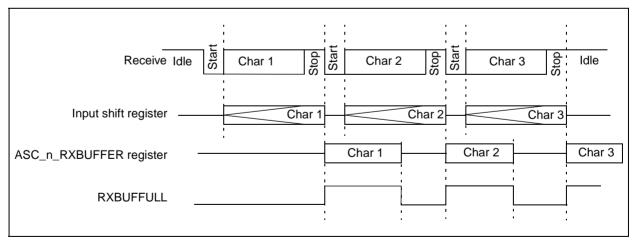

To transmit a large number of characters back to back, the driver routine initially writes 16 characters to ASC_n_TXBUFFER. Then every time a TXHALFEMPTY interrupt fires, it writes eight more. When there is nothing more to send, a TXEMPTY interrupt tells the driver that everything has been transmitted.

When receiving, the driver can use RXBUFFULL to interrupt every time a character arrives. Alternatively, if data is coming in back to back, it can use RXHALFFULL to interrupt it when there are more than eight characters in the input FIFO to read. It has as long as it takes to receive eight characters to respond to this interrupt before data overruns. If less than eight characters stream in, and no more are received for at least a time out period, the driver can be woken up by one of the two time out interrupts, TIMEOUTNOTEMPTY or TIMEOUTIDLE.

Figure 182: ASC reception

46.8 ASC operation

The UART supports both T=0 and T=1 protocol. In T=0 protocol, the reception of parity errors by either the UART or the smartcard is signalled by the automatic transmission of a NACK, where the receiver pulls the data line low, 0.5 baud clock periods after the end of the parity bit. The UART supports the reception and transmission of such NACKs. In T=1 protocol, this NACK behavior is not required, and any such behavior on the part of the UART can be disabled by setting the ASC_n_ CONTROL bit NACKDISABLE.

When the SCENABLE bit in the ASC_n_CONTROL register is set to 0, normal UART operation occurs.

46.8.1 Control registers

ASC_n_GUARDTIME

A programmable 9-bit register ASC_n_GUARDTIME controls the time between transmitting the parity bit of a character and the start bit of any further bytes, or transmitting a NACK (no acknowledge signal, see Handshaking). During the guardtime period the UART receiver is insensitive to possible start bits and the smartcard is free to send NACKs.

The guardtime is effectively the number of stop bits to use when transmitting in smart card mode. Programming a value of 0 is undefined. Any positive value < 512 is possible.

The guardtime mentioned here is different from the guardtime mentioned in ISO7816. In fact to achieve a particular guardtime value, the guardtime should be programmed with the following value:

Guardtime = guardtime + 2 (mod 256)

In particular, this applies to the special case of guardtime = 255, where effectively, the number of stop bits is 1.

If guardtime = 255 then any NACKs from the smart card might conflict with subsequent transmitted start bits, so it is assumed that the smart card is not sending NACKs in this case (T=1 protocol is being used for example). It is also important that the UART should be programmed in 0.5 stop bit mode, so that it does not see a subsequent start bit as a frame error (that is a NACK). So when guardtime = 255, the UART should be programmed in 0.5 stop bit mode.

Guardtime should always be set to at least two.

46.8.2 Transmission

In smartcard mode FIFOs can be either enabled or disabled. If FIFOs are disabled, the UART transmission behaves according to NDC requirements.

Handshaking

When the UART is transmitting data to the smartcard, the smartcard can NACK (not acknowledge) the transmission by pulling the line low, 0.5 baud clock periods into the guardtime period and holding it low for at least 1 baud clock period. The UART should also be programmed in 1.5 stop bit mode, and since it receives what it transmits, NACKs is detected as receive framing errors.

Behavior with FIFOs enabled

At about 1 baud clock period into the guardtime period, the UART knows whether or not the transmitted character has been NACKed. If no NACK has been received and the Tx FIFO is not empty, the next character is transmitted after the guardtime period.

If a transmitted character is NACKed by the receiving UART, the character is retransmitted as soon as the guardtime period expires (or if guardtime is two, an extra baud clock period later),

7939391A

and retransmission is attempted up to the number of retries set in the ASC_n_RETRIES register. If the last retry is also NACKed the Tx FIFO is emptied, putting the transmitter into an idle state, and the NKD bit is set in the ASC_n_STATUS register.

Emptying the FIFO causes an interrupt, which can be handled by software. The NKD bit in the ASC_n_STATUS register can be reset by writing to the ASC_n_TXRESET register.

All unNACKed (successfully transmitted) data is looped back into the receive FIFO. This FIFO can be read by software to determine the status of the data transmission.

Behavior with FIFOs disabled

When the smartcard mode bit is set to 1, the following operation occurs.

- Transmission of data from the transmit shift register is guaranteed to be delayed by a minimum of 1/2 baud clock. In normal operation a full transmit shift register starts shifting on the next baud clock edge. In smartcard mode this transmission is further delayed by a guaranteed 1/2 baud clock.
- If a parity error is detected during reception of a frame programmed with a 1/2 stop bit period, the transmit line is pulled low for a baud clock period after the completion of the receive frame, that is, at the end of the 1/2 stop bit period. This is to indicate to the smartcard that the data transmitted to the UART has not been correctly received.
- The assertion of the TXEMPTY interrupt can be delayed by programming the ASC_n_GUARDTIME register. In normal operation, TXEMPTY is asserted when the transmit shift register is empty and no further transmit requests are outstanding.
- The receiver enable bit in the ASC_n_CONTROL register is automatically reset after a character has been transmitted. This avoids the receiver detecting a NACK from the smartcard as a start bit.

In smartcard mode an empty transmit shift register triggers the guardtime counter to count up to the programmed value in the ASC_n_GUARDTIME register. TXEMPTY is forced low during this time. When the guardtime counter reaches the programmed value TXEMPTY is asserted high.

The de-assertion of TXEMPTY is unaffected by smartcard mode.

46.8.3 Reception

Reception can be done with FIFOs either enabled or disabled. The behavior is the same as in normal (nonsmartcard) mode except that if a parity error occurs then, providing the transmitter is idle, and the NACKDISABLE bit in ASC_n_CONTROL IS 0, the UART transmits a NACK on the TXD for one baud clock period from the end of the received stop bit. RXD is masked when transmitting a NACK, since TXD is tied to RXD and a NACK must not be seen as a start bit. If the NACKDISABLE bit in ASC_n_CONTROL is 1 then no automatic NACK generation takes place.

46.8.4 Divergence from ISO smartcard specification

This UART does not support guardtimes of 0 or 1, and does not have any special behavior for a guardtime of 255.

47 Asynchronous serial controller (ASC) registers

The registers for each ASC are grouped in a 4-Kbyte block, with the base of the block for ASC number n at the address *ASCnBaseAddress*.

Register addresses are provided as the ASCnBaseAddress + offset.

The ASCnBaseAddresses are:

UART0: 0x2083 0000,

UART1: 0x2083 1000,

There is also one enable register located in the infrared blaster block. This is provided as *IRBBaseAddress* + offset. The *IRBBaseAddress* is 0x2011 5000.

Register name	Description		Туре

 RELOADVAL

 Address:
 ASCnBaseAddress + 0x00

Type: Read/write

Reset: 1

Description: This register is the dual function baudrate generator and reload value register. A read from this register returns the content of the 16-bit counter/accumulator; writing to it updates the 16-bit reload register.

If the RUN bit of the ASC_n_CONTROL register is 1, then any value written in the ASC_n_BAUDRATE register is immediately copied to the timer. However, if the RUN bit is 0 when the register is written, then the timer is not reloaded until the first comms clock cycle after the RUN bit is 1.

The mode of operation of the baudrate generator depends on the setting of the BAUDMODE bit in the ASC_n_CONTROL register.

Mode 0

When the BAUDMODE bit in the ASC_n_CONTROL register is set to 0, the baudrate and the required reload value for a given baudrate can be determined by the following formulae:

$$BaudRate = \frac{f_{comms}}{16 \times ASCBaudRate}$$

ASCBaudRate =

16 x BaudRate

f_{comms}

where: *ASCBaudRate* represents the content of the ASC_n_BAUDRATE register, taken as an unsigned 16-bit integer,

f_{comms} is the frequency of the comms clock (clock channel PLL_CLOCK[2]). Mode 0 should be used for all baudrates below 19.2 Kbaud.

Table 108 lists commonly used baudrates with the required reload values and the approximate deviation errors for an example baudrate with a comms clock of 60 MHz.

Table 108: Mode 0 baudrate

Baudrate	Reload value (exact)	Reload value (integer)	Reload value (hex)	Approximate. deviation error
38.4 K	97.656	98	0x0062	0.35%
19.2 K	195.313	195	0x00C3	0.16%
9600	390.625	391	0x0091	0.1%
4800	781.250	781	0x030D	0.03%
2400	1562.500	1563	0x061B	0.03%
1200	3125.000	3125	0x0C35	0.00%
600	6250.000	6250	0x186A	0.00%
300	12500.000	12500	0x30D4	0.00%
75	50000.000	50000	0xC350	0.00%

Mode 1

When the BAUDMODE bit in the ASC_n_CONTROL register is set to 1, the baudrate is given by:

BaudRate =
$$\frac{ASCBaudRate \times f_{comms}}{16 \times 2^{16}}$$

where: f_{comms} is the comms clock frequency and *ASCBaudRate* is the value written to the ASC_n_BAUDRATE register. Mode 1 should be used for baudrates of 19.2 Kbytes and above as it has a lower deviation error than Mode 0 at higher frequencies.

Table 109: Mode 1 baudrates

tion: This register controls the operating mode of the UART ASCn and contains control bits for mode and error check selection, and status flags for error identification.

Programming the mode control field (MODE) to one of the reserved combinations may result in unpredictable behavior. Serial data transmission or reception is only possible when the baudrate generator run bit (RUN) is set to 1. When the RUN bit is set to 0, TXD is 1. Setting the RUN bit to 0 immediately freezes the state of the transmitter and receiver. This should only be done when the ASC is idle.

Serial data transmission or reception is only possible when the baudrate generator RUN bit is set to 1. A transmission is started by writing to the transmit buffer register ASC_n_TXBUFFER.

48 Synchronous serial controller (SSC)

48.1 Overview

The synchronous serial controller (SSC) is a high-speed interface which can be used to communicate with a wide variety of serial memories, remote control receivers and other microcontrollers. There are a number of serial interface standards for these. Two SSCs are provided on the STx5119. The SSC gives full support for the I^2C bus.

The following features are programmable:

- baudrate,
- data width,
- shift direction,
- clock polarity,
- clock phase,
- FIFO or nonFIFO modes.

The SSC shares pins with the parallel input/output (PIO) ports. It supports both half-duplex and full-duplex synchronous communication when used in conjunction with the PIO configuration.

The SSC fully supports the I^2C bus standard. The extra I^2C features include:

- multimaster arbitration,
- acknowledge generation,
- start and stop condition generation and detection,
- clock stretching.

These allow software to fully implement all aspects of the standard, such as master and slave mode, multi-master mode, 10-bit addressing and fast mode.

48.1.1 Pin connection and control

The SSC uses three signals:

- serial clock SCLK,
- serial data in/out MRST,
- serial data out/in MTSR.

The SCLK, MTSR and MRST signals are provided by two (I²C) or three (SPI) bits of a standard PIO block. Their directions (input, output or bidirectional) can therefore be configured in software using the appropriate PIO settings. Consequently the SSC does not need to provide automatic control of data pad directions and does not need to provide a bidirectional clock port.

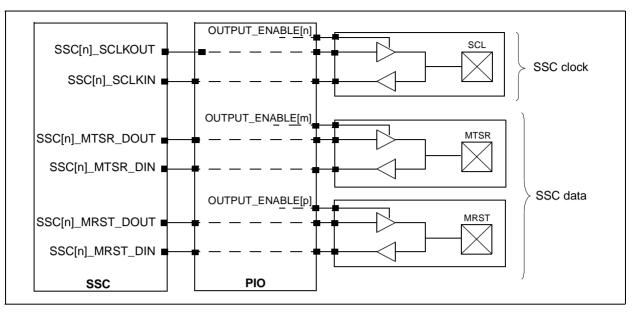

The connections between the SSC ports and the relevant PIO pins are illustrated in Figure 183. Pins are shared with PIO.

To set the SSC PIOs to their alternate functions, follow this sequence.

- 1. Set SCL and MTSR as open drain bidirectional.
- 2. Set MRST as input.
- 3. Set SCL and MTSR to logic high.
- 4. Set all SSC registers to slave mode.
- 5. Only now, when the software is ready to accept data from the master, reprogram the PIO pins to their alternate output functions.

See Table 20: Synchronous serial controller pin mapping on page 44 for further information on connecting the pins.

Figure 183: SSC to PIO connections

The pad control block inside the SSC determines which of the serial data input ports is used to read data from (depending on the master or slave mode). It also determines which of the serial data output ports to write data to (depending on the master or slave mode).

It is up to the user to ensure that the PIO pads are configured correctly for direction and output driver type (for example, push/pull or open drain).

Throughout the rest of this document, the data in and out ports is referred to as SERIAL_DATA_OUT and SERIAL_DATA_IN, where this is assumed to be the correct pair of signals dependent on the master or slave mode of the SSC.

48.2 Basic operation

The serial clock output signal is programmable in master mode for baudrate, polarity and phase. This is described in Section 48.2.1: *Clock generation* on page 486.

The SSC works by taking the data frame (two to sixteen bits) from a transmission buffer or FIFO and placing it into a shift register. It then shifts the data at the serial clock frequency out of the output pin and synchronously shifts in data coming from the input pin. The number of bits and the direction of shifting (MSB or LSB first) are programmable. This is described in Section 48.2.3: *Shift register* on page 488.

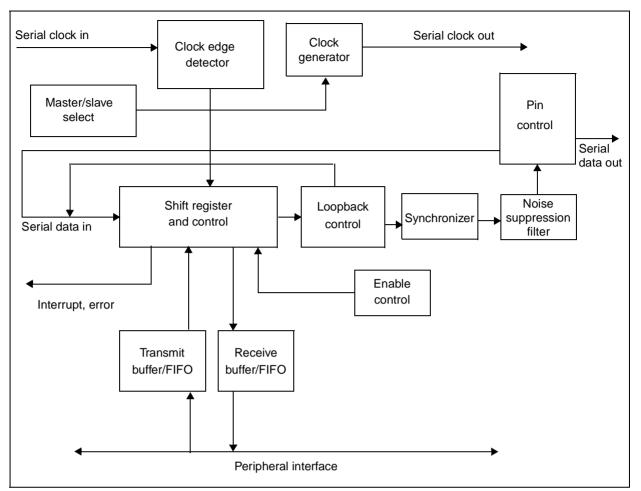

After the data frame has been completely shifted out of the shift register, it transfers the received data frame into the receive buffer or FIFO. The transmit and receive buffers are described in Section 48.2.5: *Transmit and receive buffers (nonFIFO mode)* on page 489 and Section 48.2.6: *Transmit and receive FIFOs (FIFO mode)* on page 489. In FIFO mode the FIFO is 8 bits deep and 16 bits wide while in nonFIFO mode the SSC is double buffered. This allows back-to-back transmission and reception of data frames up to the speed that interrupts can be serviced. The interrupt latency is further reduced in FIFO mode due to the additional 8-bit FIFO depth.

The SSC generates interrupts in a variety of situations:

- the transmission buffer is empty,
- the receive buffer is full,
- the transmit FIFO is half empty,
- the transmit FIFO is full,
- the receive FIFO is half full
- an error occurs.

7939391A

Figure 184: SSC architecture

The SSC can also be configured to loop the serial data output back to serial data input in order to test the device without any external connections. This is described in Section 48.2.7: *Loopback mode* on page 490.

The SSC can be turned on and off by setting the enable control. This is described in Section 48.2.8: *Enabling operation* on page 490. It can be also be set to operate as a bus master or as a bus slave device. This is described in Section 48.2.9: *Master/slave operation* on page 490.

The SSC generates interrupts in a variety of situations:

- when the transmission buffer is empty,
- when the receive buffer is full and
- when an error occurs. A number of error conditions are detected. These are described in Section 48.2.10: *Error detection* on page 490.

There are additional hardware features which can be independently enabled in order to fully support the I²C bus standard when used in conjunction with a suitable software driver. The additional I²C hardware is described in Section 48.3: *I2C operation* on page 493.

48.2.1 Clock generation

If the SSC is configured to be the bus master, then it generates a serial clock signal on the serial clock output port.

The clock signal can be controlled for polarity and phase and its period (baudrate) can be set to a variety of frequencies. At the end of the last clock period the shift register is unloaded into the receive buffer or FIFO.

For I²C operation there are a number of additional clocking features. These are described in Section 48.3: *I2C operation* on page 493.

Clock control

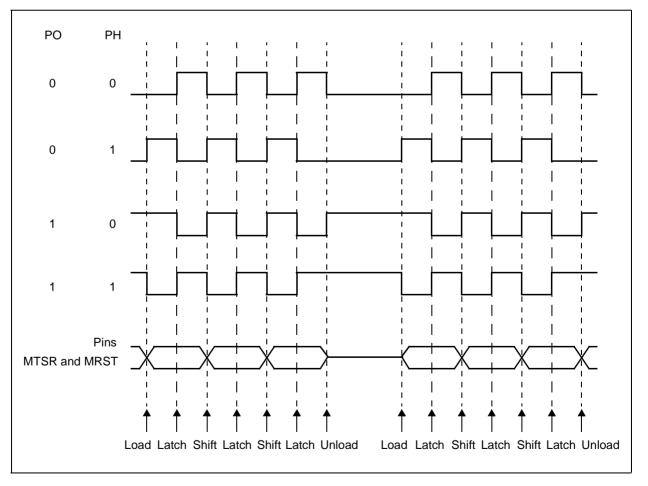

In master mode, the serial clock SCLK, is generated by the SSC according to the setting of the phase bit PH and polarity bit PO in the control register SSCnCON.

The polarity bit PO defines the logic level the clock idles at, that is, when the SSC is in master mode but is between transactions. A polarity bit of 1 indicates an idle level of logic 1, 0 indicates idle of logic 0.

The phase bit PH indicates whether a pulse is generated in the first or second half of the cycle. This is a pulse relative to the idle state of the clock line; so if the polarity is 0 then the pulse is positive going; if the polarity is 1 then the pulse is negative going. A phase setting of 0 causes the pulse to be in the second half of the cycle while a setting of 1 causes the pulse to occur in the first half of the cycle.

The different combinations of polarity and phase are shown in Figure 185.

Figure 185: Polarity and phase combinations

The SSC always latches incoming data in the middle of the clock period at the point shown in the diagram. With the different combinations of polarity and phase it is possible to generate or not generate a clock pulse before the first data bit is latched.

Shifting out of data occurs at the end of the clock period. At the start of the first clock period the shift register is loaded. At the end of the last clock period, the shift register is unloaded into the receive buffer.

48.2.2 Baudrate generation

The SSC can generate a range of different baudrate clocks in master mode. These are set up by programming the baudrate generator register SSCnBRG.

In write mode this register is set up to program the baudrate as defined by the following formulae:

$$Baudrate = \frac{fcomms}{2 \times SSCGBR} \qquad SSCBRG = \frac{fcomms}{2 \times Baudrate}$$

where SSCBRG represents the content of the baudrate generator register, as an unsigned 16-bit integer, and f_{comms} represents the comms clock frequency.

At a comms clock frequency of 60 MHz the baudrates generated are shown in Table 110.

Baudrate	Bit time	Reload value
Reserved. Use a reload value > 0	-	0x0000
5 MBaud	200 ns	0x0006
3.3 MBaud	300 ns	0x0009
2.5 MBaud	400 ns	0x000C
2.0 MBaud	500 ns	0x000F
1.0 MBaud	1 μs	0x001E
100 KBaud	10 µs	0x012C
10 KBaud	100 μs	0x0BB8
1.0 KBaud	1 ms	0x07D0

The value in SSCnBRG is used to load a counter at the start of each clock cycle. The counter counts down until it reaches 1 and then flips the clock to the opposite logic value. Consequently, the clock produced is twice the SSCnBRG number of comms clock cycles.

In read mode the SSCnBRG register returns the current count value. This can be used to determine how far into each half cycle the counter is.

Programming the SSCnBRG register with 0x0 results in the slowest clock because it has to count the entire range of the 16-bit counter. A slave device need not be programmed with any SSCnBRG value since it is always forced internally to 0. This ensures that the slave clock always follows the master clock and eradicates clock synchronization problems. The minimum programmed SSCnBRG value has to be 0x07.

For operation at even lower frequencies the clock generated according to the baudrate generator value can be further prescaled by a division factor. The prescaler register PRESCALER_BRG can be programmed with this prescaler division factor.

Hence the clock generated can be defined by:

Baudrate = $F_{CPU} / (2 * prsc)$ $prsc = F_{CPU} / (2 * baudrate)$ where prsc = brg * prescaler division factor.

48.2.3 Shift register

Confidential

The shift register is loaded with the data in the transmit buffer or FIFO at the start of a data frame. It then shifts data out of the serial output port and data in from the serial input port.

The shift register can shift out LSB first or MSB first. This is programmed by the heading control bit HB in the control register SSCnCON. A logic 1 indicates that the MSB is shifted out first and a logic 0 that the LSB shifts first.

The width of a data frame is also programmable from 2 bits to 16 bits. This is set by the BM bit field of the control register SSCnCON. A value of 0000 is not allowed. Subsequent values set the bit width to the value plus one; for example 0001 sets the frame width to 2 bits and 1111 sets it to 16 bits.

Note: For I²C the BM bit in SSCn_CON must be programmed for a 9-bit data width.

When shifting LSB first, data comes into the shift register at the MSB of the programmed frame width and is taken out of the LSB of the register. When shifting in MSB first, data is placed into the LSB of the register and taken out of the MSB of the programmed data width. This is shown for a 9-bit data frame in Figure 186.

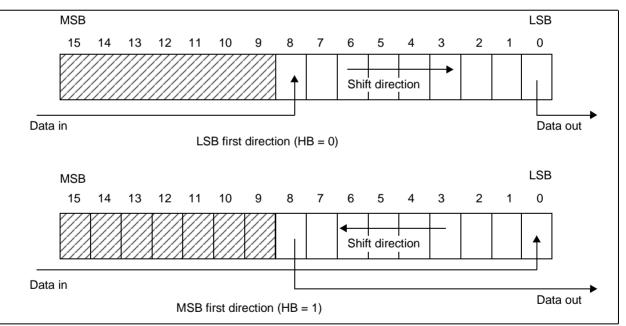

Figure 186: 9-bit data frame shifting

The shift register shifts at the end of each clock cycle. The clock pulse for shifting is presented to it from the clock generator (see Section 48.2.1: *Clock generation* on page 486). This is regardless of the polarity or phase of the clock.

When a complete data frame has been shifted, the contents of the shift register (that is, all bits shifted into the register) is loaded into the receive buffer.

There are some additional controls required on the shifting operation to allow full support of the I²C bus standard. These are described in Section 48.3: *I2C operation* on page 493.

48.2.4 Receive clock and data sampling

The serial clock and data received by the SSC is sampled after the latching edge of the input clock, the latching edge being determined by the programming of the polarity and phase bits.

The data value which is finally latched is determined by taking three data samples at the third, fourth and fifth comms clock periods after the latching data edge. The data value is determined from the predominant data value in the three samples. This gives an element of spike suppression.

48.2.5 Transmit and receive buffers (nonFIFO mode)

This mode is selected by writing 0 in the ENB_TX_FIFO bit (bit 11) and ENB_RX_FIFO bit (bit 12) respectively of the SSCnCON register. The transmit and receive FIFO's are bypassed in this mode. This is the SSC's default mode.

The transmit and receive buffers are used to allow the SSC to do back-to-back transfers; that is, continuous clock and data transmission.

The transmit buffer SSCnTBUF is written with the data to be sent out of the SSC. This is loaded into the shift register for transmission. Once this has been performed, the SSCnTBUF is available to be loaded again with a new data frame. This is indicated by the assertion of the transmit interrupt request status bit SSCTIR, which indicates that the transmit buffer is empty. This causes an interrupt if the transmit buffer empty interrupt is enabled, by setting the TIEN bit in the interrupt enable register SSCnIEN.

A transmission is started in master mode by a write to the transmit buffer. This starts the clock generation circuit and loads the shift register with the new data.

Continuous transfers of data are therefore possible by reloading the transmit buffer whenever the interrupt is received. The software interrupt routine has the length of time for a complete data frame in order to refill the buffer before it is next emptied. If the transmit buffer is not reloaded in time when in slave mode, a transmit error condition TE (see Section 48.2.10: *Error detection*) is generated.

The number of bits to be loaded into the transmit buffer is determined by the frame data width selected in the control register bit BM. The unused bits are ignored.

The receive buffer SSCnRBUF is loaded from the shift register when a complete data frame has been shifted in. This is indicated by the assertion of the receive interrupt request status bit RIR, which indicates that the receive buffer is full. This causes an interrupt if the receive buffer full interrupt is enabled, by setting the RIEN in the interrupt enable register.

The CPU should then read out the contents of this register before the next data frame has been received otherwise the buffer is reloaded from the shift register over the top of the previous data. This is indicated as a receive error condition RE. See Section 48.2.10: *Error detection*.

The number of bits which is loaded into the receive buffer is determined by the frame data width selected in the control register BM. The unused bits are not valid and should be ignored.

Note: When the first data pattern is written into the transmit buffer it is directly loaded into the transmit shift register. Again, when a transmit underrun condition occurs, the first data pattern written is loaded into the transmit shift register directly.

48.2.6 Transmit and receive FIFOs (FIFO mode)

This mode is selected by writing 1 in the ENB_TX_FIFO bit (bit 11) and ENB_RX_FIFO bit (bit 12) respectively of the SSCnCON register. In this mode the transmit buffer is bypassed. The transmit FIFO is 16 bits wide, and 8 bits deep. It is possible to write eight data patterns into it. Once filled, the FIFO cannot be overwritten with further data till one or more spaces become available.

The width of the data pattern to be transmitted is selected by setting the data width in the SSCnCON register.

The transmit FIFO may be flushed on a number of conditions, such as receiving a software reset, receiving a NACK, disabling the transmit section, arbitration loss, and bypassing FIFO mode by switching off the ENB_TX_FIFO bit in the SSCnCON register.

The receive FIFO may be flushed on a number of conditions, such as receiving a software reset, disabling the receive section, and bypassing FIFO mode by switching off the ENB_RX_FIFO bit in the SSCnCON register.

If the FIFO is filled with n data patterns (where $n \le 8$) then after all n data bytes have been transmitted the FIFO empty interrupt is generated, if enabled.

When the transmit FIFO is completely filled with eight data patterns, the FIFO full interrupt is generated, if enabled.

When the receive FIFO is completely filled with eight data patterns, the FIFO cannot be overwritten with further data till one or more data is read by the CPU.

Note: When the first data pattern is written into the transmit FIFO it is directly loaded into the transmit shift register. Again, when a transmit underrun condition occurs, the first data pattern written is loaded into the transmit shift register directly.

48.2.7 Loopback mode

A loopback mode is provided which connects the SERIAL_DATA_OUT to SERIAL_DATA_IN. This allows software testing to be performed without the need for an external bus device. This mode is enabled by setting the LPB bit in the control register, SSCnCON. A setting of logic 1 enables loopback, logic 0 puts the SSC into normal operation.

48.2.8 Enabling operation

The transmission and reception of data by the SSC block can be enabled or disabled by setting the EN bit in the control register, SSCnCON. A setting of logic 1 turns on the SSC block for transmission and reception. Logic 0 prevents the block from reading or writing data to the serial data input and output ports.

48.2.9 Master/slave operation

The control of a number of the features of the SSC depends on whether the block is in master or slave mode. For example, in master mode the SSC generates the serial clock signal according to the setting of baudrate, polarity and phase. In slave mode, no clock is generated and instead the assumption is made that an external device is generating the serial clock.

Master or slave mode is set by the MS bit in the control register, SSCnCON. A setting of logic 0 means the SSC is in slave mode, a setting of logic 1 puts the device into master mode.

48.2.10 Error detection

A number of different error conditions can be detected by the SSC. These are related to the mode of operation (master or slave, or both).

On detection of any of these error conditions a status flag is set in the status register, SSCnSTAT. Also, if the relevant enable bit is set in the interrupt enables register SSCnIEN, then an error interrupt is generated from the SSC.

The different error conditions are described as follows.

Transmit error

A transmit error can be generated both in master and slave mode. It indicates that a transfer has been initiated by a remote master device before a new transmit data buffer value has been written in to the SSC.

In other words, the error occurs when old transmit data is going to be transmitted. This could cause data corruption in the half-duplex open drain configuration.

The error condition is indicated by the setting of the TE bit in the status register. An interrupt is generated if the TEEN bit is set in the interrupt enables register.

The transmit error status bit (and the interrupt, if enabled) is cleared by the next write to the transmit buffer.

In FIFO mode this condition occurs when old data is about to be transmitted from the FIFO. It is cleared by the next write to the transmit FIFO.

Receive error

A receive error can be generated in both master and slave modes. It indicates that a new data frame has been completely received into the shift register and has been loaded into the receive buffer before the existing receive buffer contents have been read out. Consequently, the receive buffer has been overwritten with new data and the old data is lost.

The error condition is indicated by the setting of the RE bit in the status register SSCnSTAT. An interrupt is generated if the REEN bit is set in the interrupt enables register.

The receive error status bit (and the interrupt, if enabled) is cleared by the next read from the receive buffer.

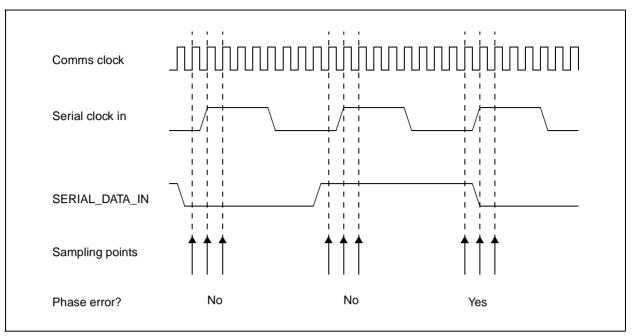

In FIFO mode this condition occurs when the receive FIFO is full and a new data byte is received. The FIFO is not overwritten, but the error condition occurs. Data bytes may be lost if the contents of the receive FIFO are not read.

Phase error

A phase error can be generated in master and slave modes. This indicates that the data received at the incoming data pin (MRST in master mode or MTSR in slave mode) has changed during the time from one sample before the latching clock edge and two samples after the edge.

The data at the incoming data pin is supposed to be stable around the time of the latching clock edge, hence the error condition. Each sample occurs at the comms clock frequency. The sampling scheme is shown in Figure 187.

Figure 187: Sampling scheme

The error condition is indicated by the setting of the PE bit in the status register. An interrupt is generated if the PEEN bit is set in the interrupt enables register. The phase error status bit (and the interrupt, if enabled) is cleared by the next read from the receive buffer.

The SSC can generate a variety of different interrupts. They can all be enabled or disabled independently of each other. All the enabled interrupt conditions are ORed together to generate

48.2.11 Interrupt mechanism The SSC can generate a independently of each oth a global interrupt signal. To determine which interrupt SSCnIEN, and determine To determine which interrupt condition has occurred, a status register SSCnSTAT is provided which includes a bit for each condition. This is independent of the interrupt enables register SSCnIEN, and determines whether the condition asserts one or more of the interrupt signals.

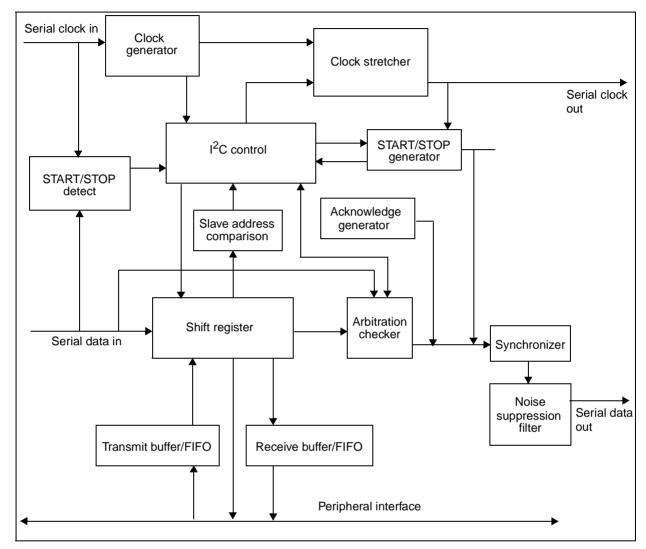

48.3 I²C operation

STx5119

This section describes the additional hardware features which are implemented in order to allow full support for the I^2C bus standard.

The architecture of the I^2C including all the I^2C hardware additions is shown in Figure 188.

Figure 188: I2C architecture

48.3.1 I²C control

There are a number of features of the I²C bus protocol that require special control.

- To allow slow slave devices to be accessed and to allow multiple master devices to generate a consistent clock signal, a clock synchronization mechanism is specified.
- START and STOP conditions must be recognized when in slave mode or multi-master mode. A START condition initiates the address comparison phase. A STOP condition indicates that a master has completed transmission and that the bus is now free.
- In slave mode (and in multi-master configurations), it is necessary to determine if the first byte received after a START condition is the address of the SSC. If it is, then an acknowledge must be generated in the ninth bit position.

Subsequently, an interrupt must be generated to inform the software that the SSC has been addressed as a slave device and therefore that it needs to either send data to the addressing master or to receive data from it.

In addition to normal 7-bit addressing, there is an extended 10-bit addressing mode where the address is spread over two bytes. In this mode, the SSC must compare two consecutive bytes with the incoming data after a START condition. It must also generate acknowledge bits for the first and second bytes automatically if the address matches.

The 10-bit addressing mode is further complicated by the fact that if the slave has been previously addressed for writing with the full 2-byte address, the master can issue a repeated START condition and then transmit just the first address byte for a read. The slave therefore must remember that it has already been addressed and must respond.

- For the software interrupt handler to have time to service interrupts, the SSC can hold the clock line low until the software releases it. This is called clock stretching.
- In master mode the SSC must begin a transmission by generating a START condition and must end transmission by generating a STOP condition. In multi-master configurations a START condition should not be generated if the bus is already busy; that is, a START condition has already been received.
- When the SSC is receiving data from another device, it must generate acknowledge bits in the ninth bit position. However, when receiving data as a master, the last byte received must not be acknowledged. This only applies to data bytes; when operating as a slave device the SSC should always acknowledge a matching address byte; that is, the first byte after a START condition.
- In multi-master configurations, arbitration must take place because it is not possible to determine if another master is also trying to transmit to the bus; that is, the START conditions were generated within the allowed time frame.

Arbitration involves checking that the data being transmitted is the same as the data received. If this is not the case, then we have lost arbitration. The SSC must then continue to transmit a high logic level for the rest of the byte to avoid corrupting the bus.

It is also possible that, having lost arbitration, it is addressed as a slave device. So the SSC must then go into slave mode and compare the address in the normal fashion (and generate an acknowledge if it was addressed).

After the byte plus acknowledge the SSC must indicate to the software that we have lost arbitration by setting a flag.

All of these features are provided in the SSC design. They are controlled by the I²C control block which interacts with various other modules to perform the protocols.

In order to program for I²C mode, a separate control register SSCnI2C is provided. To perform any of the I²C hardware features, the I²C control bit I2CM, must be set in this register. When the I²C control bit is set, the clock synchronization mechanism is always enabled (see Section 48.3.2: *Clock synchronization* on page 496). When the I²C control bit is set, the START and STOP condition detection is performed. In addition bits PH and PO of register SSC_nCON must be set to 1.

Fast mode is supported by setting the appropriate values in the following registers:

- SSCn_START_HOLD_TIME for the I²C start hold time,
- SSCn_REP_START_HOLD_TIME for the I²C repeated start hold time,
- SSCn_REP_START_SETUP_TIME for the I²C repeated start setup time,
- SSCn_DATA_SETUP_TIME for the I²C data setup time,
- SSCn_STOP_SETUP_TIME for the I²C stop setup time,
- SSCn_BUS_FREE_TIME for the I²C bus free time.

Fast mode differs from normal mode by the values set in the above registers. Hence by appropriately programming these registers operations in both modes can be achieved.

To program the slave address of the SSC the slave address register, SSCnSLAD must be written to with the address value. In the case of 7-bit addresses, only 7 bits should be written. For 10-bit addressing, the full 10 bits are written. The SSC then uses this register to compare the slave address transmitted after a START condition (see Section 48.3.4: *Slave address comparison* on page 497). To perform 10-bit address comparison and address acknowledge generation, the 10-bit addressing mode bit AD10 must be set in the SSCnI2C register (see Section 48.3.4: *Slave address comparison*).

The clock stretching mechanism is enabled for various interrupt conditions when the I²C control enable bit I2CM in register SSCnI2C is set (see Section 48.3.5: *Clock stretching* on page 498).

To generate a START condition, the I²C START condition generate bit STRTG in register SSCnI2C, must be set (see Section 48.3.6: *START/STOP condition generation* on page 498). To generate a STOP condition, the I²C STOP condition generate bit STOPG, must be set (see Section 48.3.6: *START/STOP condition generation*).

To generate acknowledge bits (that is, a low data bit), after each 8 bit data byte when receiving data, the acknowledge generation bit ACKG in register SSCnI2C, must be set. When receiving data as a master, this bit must be reset to 0 before the final data byte is received, thereby signalling to the slave to stop transmitting (see Section 48.3.7: Acknowledge bit generation on page 499).

To indicate to the software that various situations have arisen on the I²C bus, a number of status bits are provided in the status register SSCnSTAT. In addition, some of these bits can generate interrupts if corresponding bits are set in the interrupt enable register SSCnIEN.

To indicate that the SSC has been accessed as a slave device, the addressed as slave bit AAS in register SSCnSTAT, is set. This also causes an interrupt if the AASEN bit is set in register SSCnIEN.

The interrupt occurs after the SSC has generated the address acknowledge bit. In 10-bit addressing mode; the interrupt occurs after the second byte acknowledge bit, in the situations where 2 bytes of address are sent; or it occurs after the first byte acknowledge in the situation where only 1 byte is required.

Until the status bit is reset, the SSC holds the clock line low (see Section 48.3.5: *Clock stretching* on page 498). This forces the master device to wait until the software has processed the interrupt.

Interrupt bits are cleared in the CLEAR_STATUS_SSC register. Writing 1 in the corresponding location clears the interrupt.

The status bit is reset by reading from the receive buffer SSCnRBUF, when the slave is being sent data, and by writing to the transmit buffer SSCnTBUF, when the SSC needs to send data.

To indicate that a STOP condition has been received, when in slave mode, the STOP condition detected bit STOP is set. This also causes an interrupt if the STOPEN bit is set in the interrupt enable register. The STOP status bit is reset by a read of the status register SSCnSTAT. The STOP interrupt is cleared by performing a clear bit operation on the CLR_SSCSTOP bit (bit 7) of the CLEAR_STATUS_SSC register.

To indicate that the SSC has lost the arbitration process, when in a multi-master configuration, the arbitration lost bit ARBL in register SSCnSTAT, is set. This also results in an interrupt if the ARBLEN bit is set in the interrupt enable register. The interrupt occurs immediately after the arbitration is lost.

Until the status bit is reset, the SSC holds the clock line low at the end of the current data frame, (see Section 48.3.5: *Clock stretching*). This forces the winning master device to wait until the software has processed the interrupt.

The status bit is reset by a read of the status register SSCnSTAT.

To indicate that the I²C bus is busy (that is, between a START and a STOP condition), the I²C bus busy bit BUSY in register SSCnSTAT is set. This does not generate an interrupt.

48.3.2 Clock synchronization

The I²C standard defines how the serial clock signal can be stretched by slow slave devices and how a single synchronized clock is generated in a multi-master environment. The clock synchronization of all the devices is performed as follows.

All master devices start generating their low clock pulse when the external clock line goes low (this may or may not correspond with their own generated high to low transition).

The devices count out their low clock period and when finished attempt to pull the clock line high. However, if another master device is attempting to use a slower clock frequency, then it is holding the clock line low, or if a slave device wants to, it can extend the clock period by deliberately holding the clock low.

As the output drive is open-drain, the slower clock wins and the external clock line remains low until this device has finished counting its slow clock pulse, or until the slave device is ready to proceed. In the mean time, the quicker master device has detected a contradiction and goes into a wait state until the clock signal goes high again.

Once the external clock signal goes high, all the master devices begin counting off their high clock pulse. In this case the first master to finish counting attempts to pull the external clock line low and wins (because of the open drain line). The other master devices detect this and abort their high pulse count and switch to counting out their low clock pulse.

Consequently, the quicker master device determines the length of the high clock pulse and the slowest master or slave device determines the length of the low clock pulse.

This results in a single synchronized clock signal which all master and slave devices then use to clock their shift registers.

The synchronization and stretching mechanism is shown in Figure 189.

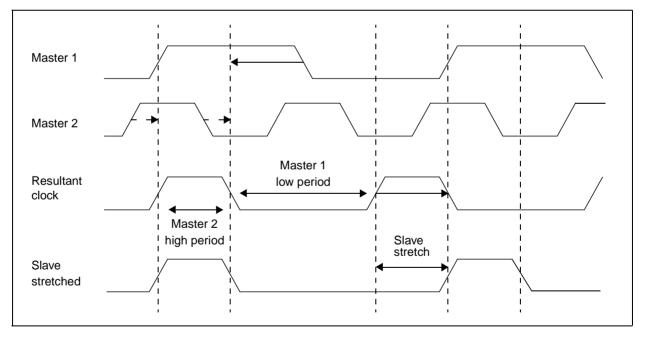

Figure 189: Synchronization and stretching

The SSC implements this clock synchronization mechanism when the I²C control bit I2CM, is enabled.

For a slave device the output clock is maintained at logic high for the master clock to propagate on the line. However when a clock stretching condition arises on it, it can force a logic low on the serial clock line and hold it low until the clock stretch is removed.

48.3.3 START/STOP condition detection

START/STOP conditions are only generated by a master device. A slave device must detect the START condition and expect the next byte (or 2 bytes in 10-bit addressing) to be a slave address. A STOP condition is used to signal when the bus is free.

A START condition occurs when the transmit/receive data line changes from high to low during the high period of the clock line. It indicates that a master device wants control of the bus. In a single master configuration, it automatically gets control. In a multi-master configuration, it begins to transmit as part of the arbitration procedure, and may or may not get control (see Section 48.3.8: *Arbitration checking* on page 499).

A STOP condition occurs when the transmit/receive data line changes from low to high during the high period of the clock line. It indicates that a master device has relinquished control of the bus (the bus is made free a specified time after the stop condition).

An additional piece of hardware is provided on the SSC to detect START and STOP conditions. This is necessary in slave mode as detection cannot be performed in time merely by programming the PIO pads. This is because there is not sufficient time for a software interrupt between the end of the START condition and the beginning of the data transmitted by a remote master.

START and STOP conditions are detected by sampling the data line continuously when the clock line is high. Minimum set up and hold times are measured by the counters.

The START hold time and the STOP setup time are programmed. To detect the start and stop times the SSC compares the setup and hold times with the programmed values.

START and STOP condition detection is enabled when the I^2C control bit I2CM is set in the I^2C control register.

When a START condition is triggered, the SSC informs the I²C control block which then initiates the address comparison phase.

When a STOP condition is triggered, the SSC sets the STOP bit in the status register. It also generates an interrupt if the STOPDEN bit is set in the interrupt enable register.

The status bit is cleared when the status register is read.

48.3.4 Slave address comparison

After a START condition has been detected, the SSC goes into the address comparison phase. If the address does not match, then the SSC ignores further data until a STOP condition is detected.

7-bit addressing

In 7-bit addressing the SSC receives the first eight bits of the next byte transmitted and compares the first seven bits against the address stored in the slave address register SSCnSLAD. If they match, the address comparison block indicates this to the l^2C control block.

This generates an acknowledge bit in the next bit position and set the addressed as slave bit AAS in the status register. An interrupt is then generated after the acknowledge bit if the addressed as slave enable bit AASEN is set in the interrupt enables register.

The eighth bit of the first byte indicates whether the SSC is written to (low) or read from (high). This is used by the control block to determine if it needs to acknowledge the following data bytes (that is, when receiving data).

10-bit addressing

When 10-bit addressing mode is selected by setting the 10-bit addressing bit AD10 in register SSCnI2C, the first seven bits of the first data byte is compared against 11110nn, where nn is the two most significant bits of the 10-bit address stored in the slave address register.

The read/write bit then determines what to do next.

7939391A STMicroelectronics Confidential 497/543

If the read/write bit is low, indicating a write, an acknowledge must be generated for the byte. The addressed as slave status bit and interrupt however are not yet asserted so, instead, the address comparator waits for the next data byte and compares this against the eight least significant bits of the slave address register.

If this matches, then the SSC is being addressed, so the second byte is acknowledged and the addressed as slave bit is set. An interrupt also occurs after the acknowledge bit if the addressed as slave interrupt enable is set.

If the address does not match, then the SSC ignores further data until a STOP condition is detected.

10-bit addressing with repeated start

If the slave has been addressed in the first frame of transmission (with full 2 bytes of address) with the read/write bit LOW (for a write), then the master device needs to send only one address byte in the next frame of transmission to address it for a read operation (read/write bit HIGH).

The SSC only acknowledges it if it has previously been addressed and a STOP condition has not yet occurred. In this case the addressed as slave bit is set after the first byte plus acknowledge and an interrupt is generated if the interrupt enable is set. The second byte in this case is sent by the SSC as this is a read operation.

If the address does not match, then the SSC ignores further data until a STOP condition is detected.

48.3.5 Clock stretching The I²C standard all the data being rece takes advantage of device driver to proo The clock stretching • By default the S write into the trareceiving data.

The I²C standard allows slave devices to hold the clock line low if they need more time to process the data being received (see Section 48.3.2: *Clock synchronization* on page 496). The SSC takes advantage of this by inserting extended clock low periods. This is done to allow a software device driver to process the interrupt conditions when in slave mode.

The clock stretching mechanism is used in the situations listed below.

- By default the SSC stretches the clock on transmit underrun. In this case software must write into the transmit buffer to release the clock stretch. 0x1FF is written if the SSC is receiving data. The SSC can be programmed to enable clock stretch on the receive FIFO/buffer full condition (by setting bit 13 in the SSCnCON register to 1). Then 0x1FF need not be written into the transmit buffer to disable clock stretch, but the receive buffer must be read instead.
- When the SSC is a master device transmitting to a slave and it receives a NACK condition the clock is stretched after the current byte with no acknowledge until the STOP or a repeated START generation bit is set on it.

If a clock stretching event occurs but no relevant interrupt is enabled then the clock is stretched indefinitely. Hence it is important that the correct interrupts are always enabled.

48.3.6 START/STOP condition generation

As a master device the SSC must generate a START condition before transmission of the first byte can start. It may also generate repeated START conditions. It must complete its access to the bus with a STOP condition.

Between STOP and START conditions, the bus is free and the clock and data lines must be held high. The I^2C control block determines this and instructs the START/STOP generator to hold the lines high between transactions for a minimum specified period.

The START/STOP generator is controlled by the START condition generate bit STRTG and the STOP condition generate bit STOPG in register SSCn I^2C .

The generator pulls the SERIAL_DATA_OUT line low during the high period of the clock to produce a START condition. In the case of a STOP condition it pulls the data line high.

However, a START condition is only generated if the bus is currently free (that is, the BUSY bit in the status register is low). This is to prevent the SSC from generating a START condition when another master has just generated one.

If a START condition cannot be generated because the bus is busy, then the generator forces the arbitration checker to generate an arbitration lost interrupt and prevent data from being transmitted for the next byte. The software interrupt handler is therefore informed of the aborted transmission when servicing the interrupt. Bit 11 (REPSTRT) of register SSCnSTAT shows that a repeated start condition has occurred.

To properly generate the timing waveforms of the START and STOP conditions, the SSC contains a timing counter which is loaded with a value programmed with the appropriate timing register. See Section 48.3.1: *I2C control* on page 493.

48.3.7 Acknowledge bit generation

For I²C operation, it is required to both detect acknowledge bits when transmitting data, and to generate them when receiving data.

An acknowledge bit must be transmitted by the receiver at the end of every 8-bit data frame. The transmitter must verify that an acknowledge bit has been received before continuing.

An acknowledge bit is not generated by a master receiver for the last byte it wishes to receive. This "not acknowledge" is used by the slave device to determine when to stop transmission or restart for a new transmission.

The acknowledge bit is generated by the receiver after the eight data bits have been transferred to it. In the ninth clock pulse, the transmitter holds the data line high and the receiver must pull the line low to acknowledge receipt. If the receiver is unable to acknowledge receipt, then the master generates a stop condition to abort the transfer.

Acknowledge bits are generated by the SSC when the acknowledge generation bit, ACKG, is set in the I²C control register. They are only generated when receiving data.

When in master mode and receiving data the ACKG bit should be set to 0 before the last byte to be received. The SSC automatically generates acknowledge bits when addressed as a slave device.

Bit 10 of the SSCnIEN register (NACKEN) permits the setting of an interrupt on a NACK condition.

48.3.8 Arbitration checking

This situation only arises when two or more master devices generate a START condition within the minimum hold time of the bus standard. This generates a valid start condition on the bus with more than one master valid.

However, a master device cannot determine if two or more masters have generated a START condition, so arbitration is always enabled. Arbitration to decide which device wins control of the bus is determined by which master is the first to transmit a low data bit on the data line when the other master wants to send a high bit. This master wins control of the bus. Therefore a master which detects a different data bit on its input to that which it transmitted must switch off its output stage for the rest of the eight bit data byte, as it has lost the arbitration.

The arbitration scheme does not affect the data transmitted by the winning master. Consequently, arbitration proceeds concurrently with data transmission and the data received by the selected slave during the arbitration process. It is valid that the winning master is actually addressing the losing master and hence this device must respond as if it were a slave device.

Arbitration is implemented in hardware by comparing the transmitted and received data bits every cycle. Loss of arbitration is indicated by the setting of the ARBL arbitration lost error flag in the status register. An interrupt also occurs if the ARBLEN bit is set in the interrupt enables register.

Loss of arbitration also causes a clock stretch to be inserted if the master which has lost arbitration has been addressed. The interrupt and the clock stretch occurs immediately after the eight bits plus acknowledge. The clock stretch is cleared when the software reads the receive buffer.

50 Programmable I/O port

50.1 Overview

The COMMS block contains one 7-bit and three 8-bit PIO blocks. These general purpose bocks are memory mapped and each bit can be configured as input, output or bidirectional. The driver may be configured as push-pull or weak pull up.

In addition any input may be compared to a stored value and used to trigger an interrupt.

Any pin may be configured as an alternative function, in this mode the pad may be routed to or from another peripheral. The alternative pin map is configured in the STx5119 by linking the appropriate COMMS bristles.

Alternative functions are detailed in Section 6.2: Alternative functions (mapped to GPIO pins) on page 32.

The PIO ports can be controlled by registers, mapped into the device address space. The registers for each port are grouped in a 4 Kbyte block, with the base of the block for port n at the address *PIOnBaseAddress*. During reset all of the registers are reset to zero.

Each PIO port has a set of registers. Each bit of a register refers to a pin in the corresponding port. These registers hold:

- the output data for the port (PIO_PnOUT),
- the input data read from the pin (PIO_PnIN),
- PIO bit configuration registers (PIO_PnC[2:0]),
- the two input compare function registers (PIO_PnCOMP and PIO_PnMASK).

Each of the registers, except PIO_PnIN, is mapped on to two additional addresses so that bits can be set or cleared individually.

- The PIO_SET_x registers set bits individually. Writing 1 in these registers sets a corresponding bit in the associated register x; 0 leaves the bit unchanged.
- The PIO_RESET_x registers clear bits individually. Writing 1 in these registers resets a corresponding bit in the associated register x; 0 leaves the bit unchanged.

51 Programmable I/O port registers

Each 8-bit PIO port has a set of eight-bit registers. Each of the eight bits of each register refers to the corresponding pin in the corresponding port.

Register addresses are provided as the PIOnBaseAddress + offset.

The PIOnBaseAddresses are:

PIO0: 0x2082 0000, PIO1: 0x2082 1000, PIO2: 0x2082 2000, PIO3: 0x2082 3000.

Table 112: Programmable I/O port registers

Register name	Description	Address offset	Туре
PIO_PnOUT	PIO output, see page 517	0x00	R/W
PIO_SET_PnOUT	Set bits of PIO_PnOUT, see page 518	0x04	WO

PIO configuration

0x20 CONFIGDATA0[7:0]	
0x30 CONFIGDATA1[7:0]	
0x40 CONFIGDATA2[7:0]	

Address: PIOnBaseAddress + 0x20 (PIO_PnC0), 0x30 (PIO_PnC1), 0x40 (PIO_PnC2)

Type: Read/write

Reset:

Description: There are three configuration registers (PIO_PnC0, PIO_PnC1 and PIO_PnC2) for each port. These are used to configure the PIO port pins. Each pin can be configured as an input, output, bidirectional, or alternative function pin (if any), with options for the output driver configuration.

Three bits, one bit from each of the three registers, configure the corresponding bit of the port. The configuration of the corresponding I/O pin for each valid bit setting is given in Table 113.

PnC2[y]	PnC1[y]	PnC0[y]	Bit y configuration	Bit y output
0	0	0	Input	Weak pull up (default)
0	0 or 1	1	Bidirectional	Open drain
0	1	0	Output	Push-pull
1	0	0 or 1	Input	High impedance
1	1	0	Alternative function output	Push-pull
1	1	1	Alternative function bidirectional	Open drain

Table 113: PIO bit configuration encoding

The PIO_PnC[2:0] registers are each mapped on to two additional addresses, PIO_SET_PnC and PIO_CLEAR_PnC, so that bits can be set or cleared individually.

			SET_PC	OMP[7:0]			

Address: PIOnBaseAddress + 0x54

Type: Write only

Description: PIO_SET_PnCOMP allows bits of PIO_PnCOMP to be set individually. Writing 1 in this register sets the corresponding bit in the PIO_PnCOMP register, while 0 leaves the bit unchanged.

PIO_SET_PnMASK Set bits of PnMASK

7	6	5	4	3	2	1	0
			SET_PM	1ASK[7:0]			

Address: PIOnBaseAddress + 0x64

Type: Write only

Description: PIO_SET_PnMASK allows bits of PIO_PnMASK to be set individually. Writing 1 in this register sets the corresponding bit in the PIO_PnMASK register, while 0 leaves the bit unchanged.

PIO_SET_F	PnOUT	Set bits of PnOUT					
7	6	5 4 3 2 1 0				0	
			SET_PC	DUT[7:0]			

Address: PIOnBaseAddress + 0x04

Type: Write only

Description: PIO_SET_PnOUT allows bits of PIO_PnOUT to be set individually. Writing 1 in this register sets the corresponding bit in the PIO_PnOUT register, while 0 leaves the bit unchanged.

52 Electrical specifications

52.1 Absolute maximum ratings

Table 114: Absolute maximum ratings

Symbol	Parameter	Min	Max	Units
VDD33 _{MAX}	DC supply voltage		6.4	V
VDD _{MAX}	DC supply voltage		2.1	V
VI5 _{MAX}	DC voltage on input, output and bidirectional 5 V tolerant pins	GND - 0.5 ¹	5.5 ²	V
VO3 _{MAX}	DC voltage on input, output and bidirectional 3.3 V tolerant pins	GND - 0.5 ¹	VDD + 0.5 ³	V
IO _{MAX}	DC output current		20	mA
TS _{MAX}	Storage temperature (ambient)	-55	125	°C
TA _{MAX}	Temperature under bias (ambient)	-55	125	°C

1. AC transient undershoot of 0.7 V below GND -0.5 V (that is -1.2 V) is allowed for a maximum period of 2 ns.

- 2. AC transient overshoot of 0.7 V above 5.5 V is allowed for a maximum period of 2 ns.
- 3. AC transient overshoot of 0.7 V above VDD33 + 0.5 V is allowed for a maximum period of 2 ns.

Confidential vote:

Stresses greater than those listed in Table 114 may cause permanent damage to the device. This is a stress rating only and functional operation of the device at these or any other conditions above those indicated in the operating sections of this specification is not implied. Exposure to absolute maximum rating conditions for extended periods may affect reliability.

2 Operating conditions

Table 115: Operating conditions

Symbol	Parameter	Min	Typical	Max	Units	Notes
VI	Input voltage (3.3 V I/O only)	0		3.6	V	1
VI35	Input voltage (3.3 V / 5 V tolerant I/O)	0		5.5	V	2
CL	Load capacitance per pin			100	pF	
ТА	Operating temperature (ambient)	0		70	°C	
PD	Maximum power dissipation at VDD33 = 3.6 V and VDD = 1.32 V			1.35	W	
PD _{LP}	Power dissipation (low power mode)			900	mW	

1. Excursions beyond the supplies are permitted but not recommended. AC transient overshoot and undershoot are permitted up to the limits in Table 114.

2. AC transient overshoot and undershoot is permitted up to the limits in Table 114.

52.3 Standard pads DC specifications

The standard pads concern all digital interfaces except LMI interfaces.

Symbol	Parameter	Min	Typical	Мах	Units	Notes
VDD	Positive core supply voltage	1.08	1.2	1.32	V	
VDD33	Positive I/O supply voltage	3.0	3.3	3.6	V

	Output fall time	Between 0.8 and 2 V			1.2	ns

Table 117: LMI pads AC/DC specifications

52.5 Targeted power consumption

Table 118: Targeted power consumption

Power	Consumption
VDD 1.2 V	350 mA
VDD33LMI 3.3V	100 mA
VDD 3.3V	20 mA to 120 mA ¹
VDDDAC (total) V	40 mA
VDDAADA V	30 mA

1. The value depends on the number of peripherals and PIO used.

52.6 Audio DAC specifications

Table 119: Audio DAC supply specifications

Symbol	Parameter	Min	Тур	Max	Units	Notes
VDDAADAC	DC analog supply voltage	3.0	3.3	3.6	V	

52.6.1 Audio DAC parameters

Parameter	Typical	Unit
SNR	94 dB at -3 dBFS	dB
	114 dB at -60 dBFS	
Dynamic Range ¹	-95	dB
Signal to {THD + Noise}	85	dB
Signal to Total Harmonics Distortion	-92	dB
Noise Floor ²	-108	dBv
Interchannel Isolation	-80 at 1 kHz	dB
Interchannel Gain Mismatch	0.1	dB
Out of band noise	-70	dB

1. The specified value is obtained by adding 60 dB to the measured THD+N at full scale -60dB, with A-Weighting Filter.

2. The specified value is obtained when the digital code is "00H"

52.7 Video DAC parameters

Table 120: Video DAC parameters

Parameter	Min	Тур	Max	Unit
Differential non linearity (DNL)	-1		1	LSB
Integral non linearity (INL)	-2		2	LSB
Dynamic current ¹	7	8	9	mA
Output voltage (max)			1.6	V DC
Analogue 3dB bandwidth	6			MHz
Rise and Fall time			10	ns
DAC to DAC matching ²		+/- 1	+2	%
Conversion rate	27			MHz
SNR, BW=10MHz, Fclk=80MHz		50		dB
THD, Fout=5MHz, Fclk=80MHz		-50		dB
(Vbandgap)	-4%	1.23	+4%	V
Cross-talk				
Gain variation		10		%
Syncro/blanking/white levels				

1. The output current of 8mA is with typ bandgap voltage (1.23V) and RREF = 10Kohms

2. These figures can be significantly improved (overall variation ~3%) by using the trimming control in the DENC. The gain control has a resolution of 0.75%

53 **Timing specification**

This chapter contains I/O specifications for the following interfaces:

- system (reset, CLK27, low power mode) on page 523,
- 16-bit LMI (local memory) on page 525,
- 16-bit FMI (flash and peripherals) on page 530,
- transport (PTI) incorporating multiplexed D1 input and YUV out on page 533,
- TAP on page 534,
- PIO port, including digital I/O on page 536,
- digital I/O:
 - (DMA requests on page 536,
 - asynchronous serial controller on page 536,
 - synchronous serial controller on page 537,
 - infrared receiver/transmitter on page 538,
- general power supply requirements on page 538.

Load capacitance on the tester differs according to the way measurements are taken. In standard mode it is evaluated to approximately 50 pF whereas for high speed measurements with 50 Ω termination the figure is around 15 pF.

The default drive strength setting used for all characterization and simulation work is 25 pF.

The t_{RSTHRSTL} value in the following figure and table is for power-on reset when the device is

Figure 190: Reset timings

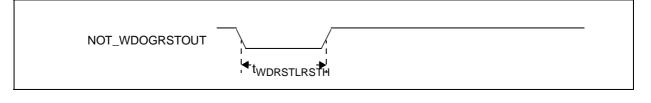

Table 122: Reset timings figures

Symbol	Parameter	Min	Nom	Max	Units
t _{RSTLRSTH}	NOTRST pulse width low ¹	10	-	-	ms

1. This is to allow for crystal oscillator start-up times which can be long.

53.1.2 Watchdog reset out

ل ۲۸

Table 123: NOT_WDOGRSTOUT figures

Symbol	Parameter	Min	Nom	Мах	Units
twdrstlrsth	NOT_WDRSTOUT pulse width low	10	-	NOT_RESET + 10	ms

53.1.3 Low power mode timings

Table 124: LPCLKIN requirements

	Min	Max
Clock frequency	1/6 of the communications clock	50 kHz

Note: The LPM clock is also available as an output, as an alternative function on PIO2[5].

53.1.4 System clock

External 27 MHz clock

Either a 27 MHz clock can be fed into CLK27IN, or a crystal pi network may be connected between CLK27IN and CLK27OSC. The crystal option and internal VCO is the option recommended by STMicroelectronics.

Crystal requirements

The external 27 MHz crystal has the following requirements:

- 27.000 MHz fundamental frequency,
- parallel resonance,
- 40 ppm accuracy.

53.2 LMI (SDRAM) interface specifications

Figure 192: Synchronous DRAM power-on sequence

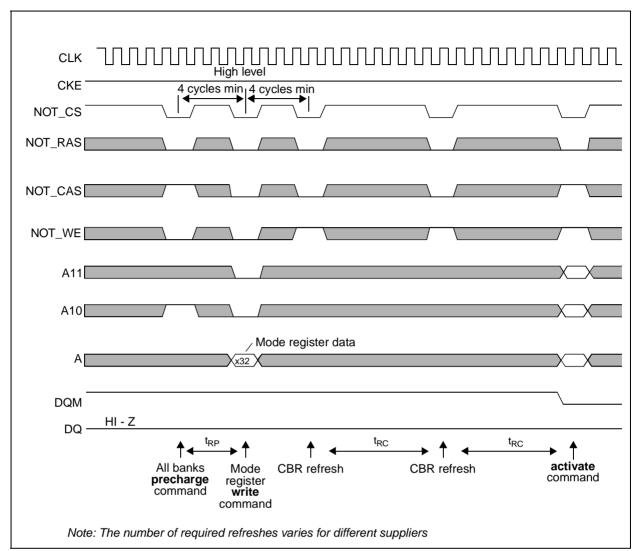

Figure 193: AC parameters for read (synchronous DRAM)

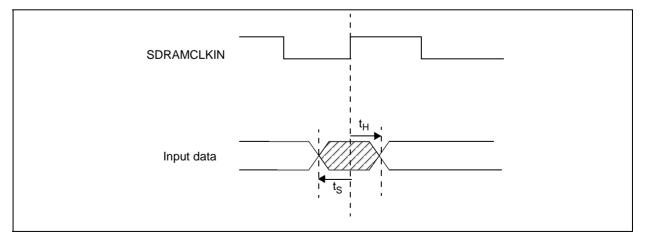

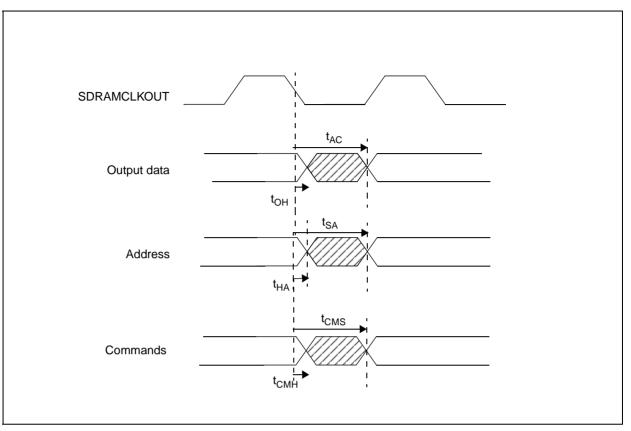

Figure 194: AC parameters for write (synchronous DRAM)

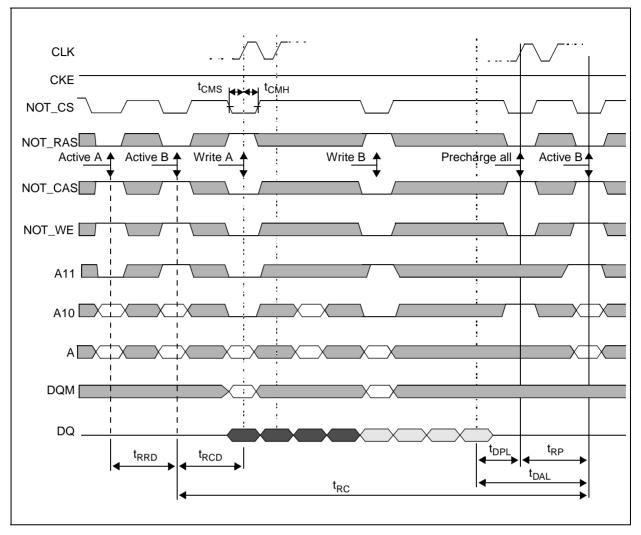

Figure 195: Synchronous DRAM write (burst length = 4, CAS latency = 3)

In Table 125, the unit T is the period of the memory subsystem clock (typically 8.23 ns / 121.5 MHz).

Symbol	Parameter	Min	Max	Units	Notes
t _{RP}	active to pre command period	3		Т	
t _{RC}	ref to ref/active command period	12		Т	
t _{CK}	Clock cycle time	7.4		ns	1
t _{CH}	Clock high level width			ns	2
t _{CL}	Clock low level width			ns	b
t _S	Data input setup time	1.9		ns	
t _H	Data input hold time	1		ns	
t _{AC}	Output data access time		2.0	ns	
t _{OH}	Output data hold time	-2.0		ns	3
t _{SA}	Address access time		2.0	ns	
t _{HA}	Address hold time	-2.0		ns	с

t _{RCD}	Delay time active to read/write command	4		Т	
t _{RRD}	active(a) to active(b) command period	4		Т	
t _{DAL}	data-out to active command period	5		Т	
t _{DPL}	data-out to precharge command period	2		Т	
t _{RAS}	active to precharge command period	9		Т	

Table 125: Synchronous DRAM read and write

1. Maximum clock rate is 135 MHz.

2. A 50% duty cycle is recommended.

3. Negative values mean that the measured event is before the falling edge of MEMCLKOUT.

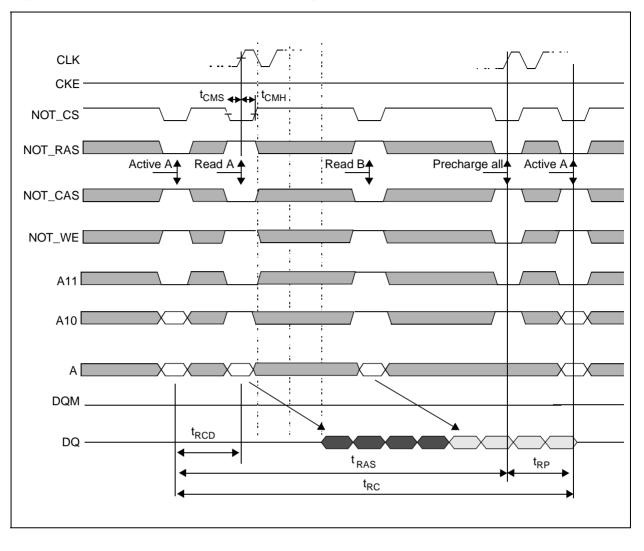

Figure 196: Synchronous DRAM read (burst length = 4, CAS latency = 3)

53.3 FMI

The FMI supports synchronous accesses to SFlash $\ensuremath{^{\rm TM}}$ and also access to asynchronous peripherals.

All figures quoted in this section are under the default configuration described at the beginning of this chapter.

53.3.1 Synchronous devices

Outputs are generated and inputs sampled with respect to the rising edge of the bus clock. The static timing characteristics for all FMI pins are shown in Figure 197 and Table 126. These values are static offsets within a bus clock cycle.

Figure 197: FMI interface timings for synchronous transactions

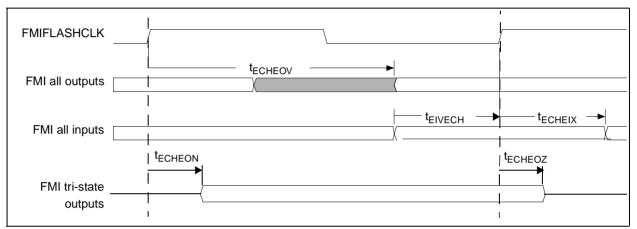

Table 126: FMI synchronous interface parameters

Output values assume a 25 pF external load						
Symbol	Description	Min (ns)	Max (ns)			
t _{ECHEOV}	Bus clock rising edge to valid output data	1.0	3.0			
t _{EIVECH}	Input valid to rising clock edge (input set-up time)	4.0	-			
t _{ECHEIX}	Rising clock edge to input invalid (input hold time)	-1.0	-			
t _{ECHEON}	Rising clock edge to tri-state outputs	2	-			
t _{ECHEOZ}	Rising clock edge to outputs tri-state	-	4			

Table 126 assumes an external load of 25 pF. If larger loads are used t_{ECHEOV} must be derated accordingly, as in Figure 198.

Bus cycle time is programmed as a division (1, 2 or 3) of the FMI subsystem clock frequency. When configured as a clock master, the STx5119 FMI may be programmed over a range of frequencies up to 108 MHz.

53.3.2 Asynchronous memory/peripherals

The FMI strobes are programmed in terms of internal clock phases, that is to say with half cycle resolution. The clock to output delay for all outputs (address, data and strobes) are closely matched, with a tolerance of ± 0.3 ns using equal loads (nominal 25 pF). Any additional skew is dependent on the external load spread. Increasing the load delays the signal. The signals are delayed as in Figure 198.

The input latchpoint for a read access is determined by the number of programmed FMI subsystem clock cycles for the latchpoint. The correction in Figure 198 allows the latchpoint to be measured from the active strobe, assuming the strobe has a 25 pF external load. For larger loads adjust according to the derating graph in Figure 198.

For example if all signals are equally loaded with 25 pF, the time between the address bus switching and a strobe switching is only *n* programmed phases ± 0.3 ns. For a write cycle, the time between the address bus switching and the data bus switching is *n* programmed phases of data drive delay ± 0.3 ns. For a read cycle the data is latched by the STx5119 at the programmed number of FMI subsystem clock cycles from the end of the access plus a latch point correction time. The latch point correction time is 3 ns + load correction of the output signal used as a reference. In this case this is 3 ± 0.3 ns. This ensures that the read hold time is always a minimum of 0 ns, guaranteed by design.

Figure 198: Asynchronous access: read

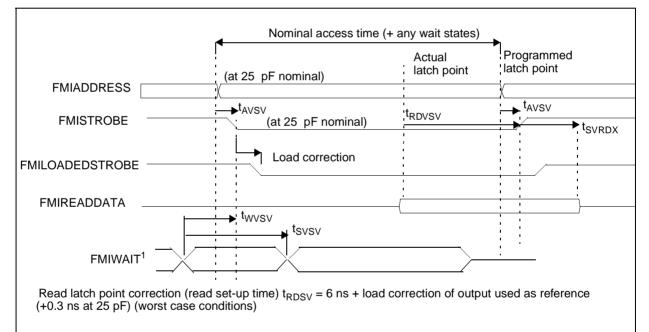

Figure 199: Asynchronous access: write

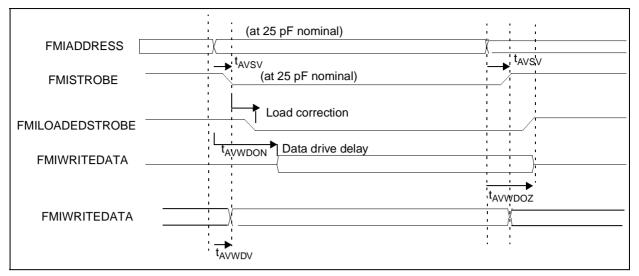

Table 127: FMI asynchronous access mode timings

Values as	sume a 25 pF external load			
Symbol	Description	Min (ns)	Max (ns)	Notes
t _{AVSV}	Address valid to output strobe valid	-0.3	0.3	1,2
t _{RDVSV}	Read data valid to strobe valid (read set-up time)	6.3	-	3
t _{SVRDX}	Read data hold after strobe valid (read hold time)	0	-	4
t _{WVSV}	Wait valid to strobe valid (wait set-up time)	6.3	-	5,6
t _{WVWV}	Minimum wait valid time (before state change)	>1T	-	6
t _{AVWDON}	Address valid to write data valid from tri-state	-	2.3	7
t _{AVWDOZ}	Address valid to write data valid to tri-state	-	4.3	
t _{AVWDV}	Address valid to write data valid from on state	-0.3	0.3	8

1. Skew plus nominal N programmed FMI subsystem clock cycles of strobe delay.

- Example: if load on address is 25 pF and load on strobe is 50 pF, tAVSV is -0.3 + 0.8 ns minimum, 0.3 + 0.8 ns maximum = 0.5 ns minimum, 1.1 ns maximum.
 If the load on the address is 50 pF and the load on the strobe is 25 pF, tAVSV is -0.3 ns 0.8 ns minimum, 0.3 ns -0.8 ns maximum = -1.1 ns minimum, -0.5 ns maximum.
- 3. Skew from nominal programmed read latch point.
- 4. Minimum values are guaranteed by design.
- 5. Use an output strobe programmed to fall on the rising edge of the FMI subsystem clock, as a reference. FMIWAIT is sampled at the end of the first and subsequent clock cycles of the access, except for the penultimate cycle.
- 6. FMIWAIT is synchronized by the FMI pad logic using the FMI subsystem rising clock edge, so violating set-up time just means that if the signal was sampled low, no wait state is inserted. If sampled high a wait state is inserted. The signal is resampled on the next FMI subsystem clock cycle, where T is the FMI subsystem clock period.
- 7. Skew from nominal programmed phases of data drive delay.
- 8. No data drive delay.

53.4 Transport stream timings

Each live input can tolerate 27 Mbyte/s in parallel mode and 100 Mbit/s in serial mode.

In serial mode, the data is arriving on TSINDATA[7] only. See Table 12: *Transport stream 0 pins* on page 39 for alternative functions.

Table 128: Maximum bit/byte clock frequencies supported by TSIS

Transport steam format	Max bit/byte clock frequency	Period
Parallel	27 MHz	37 ns
Serial	100 MHz	10 ns

Figure 200: Parallel transport stream input timings (27 Mbyte/s input rate)

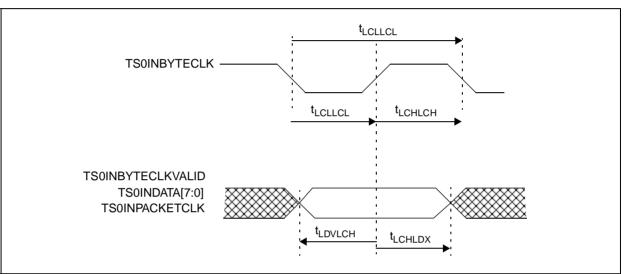

Table 129: TSIN timings: parallel input mode

Symbol	Parameter	Min	Nom	Max	Units
t _{LCLLCL}	TS0INBYTECLK period	37	-	-	ns
t _{LCHLCH}	TS0INBYTECLK pulse width high	10	-	-	ns
t _{LCLLCL}	TS0INBYTECLK pulse width low	10	-	-	ns
t _{LDVLCH}	TS0IN signals valid to TS0INBYTECLK high	10	-	-	ns
t _{LCHLDX}	TS0IN signals hold after TS0INBYTECLK high	0	-	-	ns

53.5 TAP timings

Figure 201: TAP timings

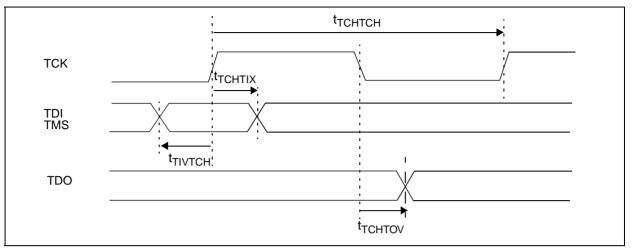

Table 130: TAP timings

Symbol	Parameter	Min	Nom	Max	Units
t _{TCHTCH}	TCK period	20	-	-	ns
t _{TIVTCH}	TAP inputs set-up time ¹	4	-	-	ns
t _{тснтіх}	TAP input hold time ¹	4	-	-	ns
t _{TCHTOV}	TCK low to TAP output valid	-	-	20	ns

1. Set-up and hold time should be equivalent to 30% of the given TCK period.

There are three other DCU signals, NOT_TRST, DCUTRIGGERIN and DCUTRIGGEROUT. The latter two have dedicated pins on the STx5119. These signals can be considered asynchronous and therefore have no timing constraints. DCUTRIGGERIN need only be asserted long enough for the CPU to sample it.

53.6 Audio

53.6.1 S/PDIF

The S/PDIF output is Manchester encoded and hence self-clocking. There are no requirements on this signal relative to other chip signals.

53.6.2 PCM decoder output interface

The PCM decoder output interface can be clocked off both edges.

Figure 202: PCM data output

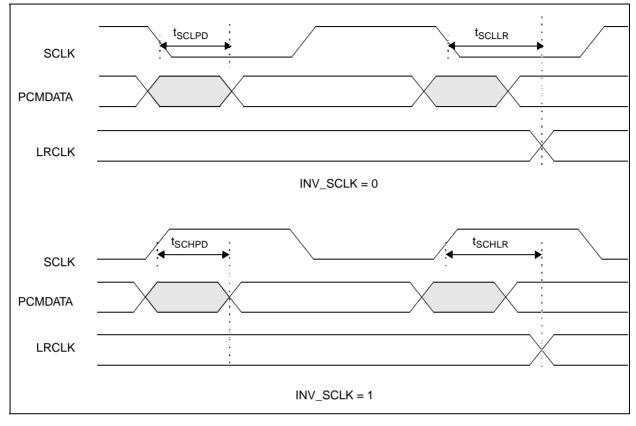

Table 131: PCM data output

Symbol	Parameter	Min	Мах	Units
t _{SCLPD}	SCLK low to PCMDATA valid	-	10	ns
t _{SCLLR}	SCLK low to LRCLK	-	10	ns
t _{SCHPD}	SCLK high to PCMDATA valid	-	50	ns
t _{SCHLR}	SCLK high to LRCLK	-	50	ns

53.7 **General PIO**

Figure 203: General PIO timings

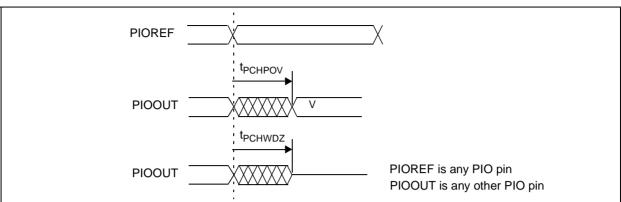

Table 132: General PIO timing parameters

Symbol	Parameter	Min	Max	Units
t _{PCHPOV}	PIOREF transition to PIO output valid	-20.0	0.0	ns
t _{PCHWDZ}	PIO tri-state after PIOREF transition	-20.0	5.0	ns

53.8.1 Digital I/O 53.8.1 DMA requests A pair of requests asynchronous. No pins. 53.8.2 ASC A pair of request signals for DMA (DMAREQ[1:0]). These are used mostly by the FDMA and are asynchronous. Note that INTERRUPT2 and INTERRUPT3 are the alternative function of these

There are two UARTs. These are, by definition, asynchronous and have no skew or timing constraints. The mapping of the UART pins is shown in Table 18: Asynchronous serial controllers pin mapping on page 43.

53.8.3 SSC

There are two SSC interfaces. The maximum bit rate for SPI is 10 Mbit/s. The SSC supporting SPI can be configured to sample on either the rising or falling edge. Data is sampled using a majority scheme based on communications clock sampling, therefore timing constraints are defined in periods of the communications clock. The pin mapping is shown in Table 20: Synchronous serial controller pin mapping on page 44.

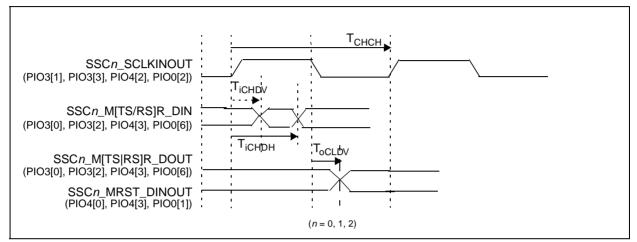

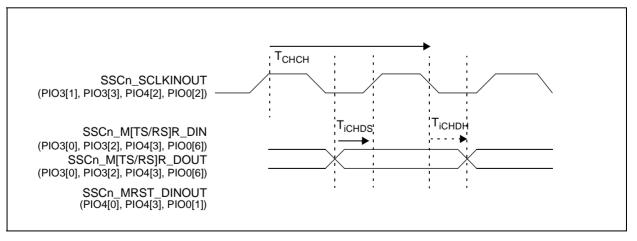

Table 133: SSC timing parameters

Symbol	Parameter	Min ¹	Nom	Max ¹	Units
t _{CHCH}	Input clock period (rising-rising)	-	200	-	ns
t _{iCHDV}	Required time elapsed from rising (capture) clock edge to input data stable.	-	-	2T	ns
t _{iCHDH}	Required time elapsed from rising (capture) clock edge for input data to hold.	6T + 10	-	-	ns
t _{oCLDV}	Required time elapsed from falling (launch) clock to output data stable.	2T	-	3T + 10	ns

1. T is 1 period communications clock, 16.7 ns for standard 60 MHz communications frequency.

Figure 205: SSC I²C clock relationship waveform

		High	speed	l	Fast me	ode		STD m	ode		
Symbol	Parameter	Min	Ту р	Max	Min	Тур	Max	Min	Тур	Max	Units
t _{CHCH}	Input clock period	589	-	-	2500	-	-	10000	-	-	ns
t _{iCHDS}	Data ¹ set-up time	10	-	-	100	-	-	250	-	-	ns
t _{iCHDH} 1	Data hold time	0 ²	-	150	300	-	900	300	-	3450	ns
T _{CL}	SCLK low period	320	-	-	1300	-	-	4700	-	-	ns
Т _{СН}	SCLK high period	120	-	-	600	-	-	4000	-	-	ns
TrTf ³	SDA/SCLK rise/ fall	20	-	80	20+ 0.1C _b ⁴	-	300	-	-	1000	ns

Table 134: SSC I²C timing parameters

1. The data is launched during the low period of the clock but captured during the high period of the clock. There is no clock inversion.

2. A device must internally provide a Data hold time to bridge the undefined part between VIH and VIL of the falling edge of the SCLK signal.

3. Both SDA and SCLK are considered data signals and are synchronized w.r.t the communications clock. All parameters are fully programmable in H9 IP block.

4. Capacitive load C_b, for clock and data bus is 400 pF maximum for I^2C . (10 pF per I^2C device) Other devices, such as a serial EEPROM, have a typical value of 8 pF.

There are two inputs and two outputs. No constraints on timing or skew. Mapping is shown in Table 22: Miscellaneous on page 46.

General power supplies

Table 135: Power supply requirements

Supply	Pin name	Comments
3.3 V I/O supply	VDD33	± 10%
1.2 V core supply	VDD12	± 10%
3.3 V LMI supply	VDD33LMI	± 10%
3.3 V audio DAC supplies	VDDAADAC	60 mV ripple on 5 V ¹
3.3 V video DAC RGB	VDDVDACRGB	30 mV ripple
3.3 V video DAC YCC	VDDVDACYCC	30 mV ripple
1.2 V frequency synthesizers	VCCAFS	30 mV ripple
1.2 V system PLLs	VCCAPLL1 VCCAPLL2	50 mV ripple 50 mV ripple

1. Figures are from simulation data.

Note: Only VDD is shown in the table. Where a supply has a particular ripple requirement it is assumed that the corresponding VSS/GND pin is subject to the same.

53.9.1 Signal overshoot and undershoot.

Maximum undershoot is -1.2 V for 2 ns maximum. Maximum overshoot is 4.3 V for 2 ns maximum (VDD33).
