

The WL800 is a low power single chip frequency synthesiser. The circuit is fabricated on Mitel Semiconductor HG process and operates from a supply voltage of 2.7 - 3.6V. It is designed to work with the Mitel Semiconductor WL600C RF and IF circuit and the WL102 WLAN controller chip which together make up the DE6038 frequency hopping Wireless Local Area Network (WLAN) transceiver.

**FEATURES**

- Low power consumption
- 2.5GHz input
- 144 frequencies, 1MHz steps (20MHz crystal)
- Forms complete phase locked loop using external VCO and loop components
- Serially programmed via 3 wire bus
- Contains anti-modulation circuit
- Part of DE6038 Chip-set (WL600C, WL102)

Note: 1. Standby to operate time refers to the time for internal current references to become operational.

## FUNCTIONAL DESCRIPTION

### Reference Frequency

The reference frequency is generated using a 20MHz crystal in conjunction with an on chip oscillator maintaining circuit. A buffer circuit provides a low level voltage output signal at the crystal frequency to drive the logic in the protocol and control chip. The crystal frequency is divided by 20 to provide the reference signal to the phase comparator.

### Counters / Dividers

An external oscillator is used to feed the input of the preamplifier in the synthesiser, (this isolates the counters from the oscillator and reduces the level of drive signal required by the synthesiser). The output of the preamplifier drives a dual modulus prescaler with ratios of 48/49, which in turn then drives the standard A-M counter arrangement. The A counter then provides the modulus control signal back to the prescaler. The counter system has an overall division ratio given by the formula  $MN+A$  where N is the lower divide ratio of the prescaler (48).

The divide ratio of the M and A counters is programmable to allow the oscillator to be tuned over the required frequency range of 144 channels at 1MHz spacing. The M count ratio can be programmed over the range 49 to 52 and the A counter from 1 to 48 giving a total divide ratio from 2353 to 2544 which is greater than necessary to tune the required frequency range.

### Programming

The programming data for the synthesiser is entered via a three wire serial data bus consisting of Enable, Clock and Data signals.

The enable signal is taken low at the start of the programming sequence and remains low for the duration of the 8 serial data bits. A positive clock edge is required to strobe each data bit into the input register. When all 8 data bits are entered, the enable pin is taken high forcing the counters to zero and preloading the new count data when the counter is next clocked. The charge pump is disabled for a short period after the enable pin goes low to prevent glitch energy being transferred to the VCO.

### Phase Detectors

A conventional digital phase frequency detector incorporating dead band suppression is used in conjunction with a charge pump to steer the VCO. An internal op-amp maintains the charge pump pin at the same voltage as the charge pump reference by virtual earth principles. The op-amp is split into two parts with the first section having a relatively low current drive capability but including the high gain stages of the amplifier. The second stage has a controlled voltage gain of 1/3 but high input impedance and low output impedance. This minimises loading to the high output impedance of the first stage and provides sufficient drive current via the loop filter to maintain virtual earth at the charge pump output. The output from the first stage is designed to swing close to the positive and negative rails so as to provide maximum voltage swing to the varactor controlling the VCO. A compensating capacitor can be connected to this point to stabilise the amplifier.

A lock detect output (active low) is provided to give an indication to the controller that the phase locked loop is locked, preventing transmission on illegal frequencies.

### Antimodulation

The WL800 contains a data buffer circuit which accepts transmit data from the CMOS controller circuit and converts the CMOS input to a tristate current output for driving the transmit spectrum shaping filter. The buffer gives zero current for a logic "1" input, a high current (+2I) for a logic "0" and a current midway between the two (+I) for use during the transmit amplifier power up/down period and during receive. This function prevents the synthesiser centring its frequency on either a logic "1" or "0" and removes the possibility of over-modulation at the start of a transmission. The amplitude of the output current and therefore modulation index of the radio is controlled by an external resistor connected to ground. A data compensation path is included which counteracts the tendency of the PLL to drift back to centre frequency when the data is non-white. This is achieved by charging an external capacitor with a current +I when data is low, and discharging it by a current -I when data is high. The capacitor voltage, which then represents an integrated form of the data is converted to a current via a buffer and an external resistor (RCOMP), and fed into the Loop Filter in addition to the Phase Detector output. During Receive Mode, the capacitor is charged to the Charge Pump Reference voltage.
